Abstract

We present an adapted gas chromatograph capable of measuring simultaneously and semi-continuously the atmospheric mixing ratios of the greenhouse gases CO₂, CH₄, N₂O and SF₆ and the trace gas CO with high precision and long-term stability. The novelty of our design is that all species are measured with only one device, making it a very cost-efficient system. No time lags are introduced between the measured mixing ratios. The system is designed to operate fully autonomously which makes it ideal for measurements at remote and unmanned stations. Only a small amount of sample air is needed, which makes this system also highly suitable for flask air measurements. In principle, only two reference cylinders are needed for daily operation and only one calibration per year against international WMO standards is sufficient to obtain high measurement precision and accuracy.

The system described in this paper is in use since May 2006 at our atmospheric measurement site Lutjewad near Groningen, The Netherlands at 6°21′ E, 53°24′ N, 1 m a.s.l. Results show the long-term stability of the system. Observed measurement precisions at our remote research station Lutjewad were: ±0.04 ppm for CO₂, ±0.8 ppb for CH₄, ±0.8 ppb for CO, ±0.3 ppb for N₂O, and ±0.1 ppt for SF₆. The ambient mixing ratios of all measured species as observed at station Lutjewad for the period of May 2007 to August 2008 are presented as well.

1 Introduction

The effects of Global warming are becoming more and more notable every year. According to the Intergovernmental Panel for Climate Change (IPCC) eleven of the twelve years between 1995 and 2006 rank among the warmest years since 1850. The global average surface temperature has already increased by 0.74°C between the years 1906 and 2005 (IPCC, 2007). Most of the observed temperature increase since the mid-20th century can probably be attributed to the observed increase of anthropogenic green-
house gas mixing ratios (IPCC, 2007). Since 1750, the radiative forcing caused by the long-lived greenhouse gases (LLGHGs) CO₂, CH₄ and N₂O is estimated to be: 1.66, 0.48 and 0.16 Wm⁻², respectively, causing a combined radiative forcing of Earth’s climate which is unprecedented in at least 10 000 years (IPCC, 2007).

Assessing the above, our goal was to develop a facility for measuring ambient mixing ratios of the three most important LLGHGs: CO₂, CH₄ and N₂O. This facility was to comply with the following: in-situ measuring the ambient mixing ratios with sufficient temporal resolution (at least several measurements per hour) and a high reliability, low in maintenance, relative easy to operate and autonomously operating. The latter is an essential feature at remote and unmanned stations. Furthermore it had to comply with the recommendations for measurement precision as given by the World Meteorological Organization’s Global Atmosphere Watch (WMO-GAW). The WMO gives recommendations for inter-laboratory comparability as follows: CO₂ ±0.1 ppm, CH₄ ±2 ppb, N₂O ±0.1 ppb, (WMO, 2005, 2001). Hence, measurement precision and accuracy for one single measurement has to meet at least these requirements. We further desired the system to be relatively inexpensive in order to be attractive (cost-benefit wise) for other research groups as well and potentially improve global data coverage.

Besides measuring CO₂, CH₄ and N₂O we desired the system also to measure two other components: CO and SF₆. CO is an important molecule in tropospheric chemistry mainly for its reaction with OH (Fishman and Crutzen, 1978). Because CO and CH₄ both are oxidized in the troposphere by the OH radical, changes in background mixing ratio of either one of them will affect the other. Moreover, since any carbon-containing fuel combustion process with CO₂ as an end product also delivers CO, the sources of CO are very closely linked to those of fossil fuel CO₂ (Gamnitzer et al., 2006). The ratio of CO: fossil fuel CO₂ is thus a direct measure for combustion quality on a regional scale (Zondervan and Meijer, 1996; Meijer et al., 1996). Once this ratio is known, CO can be used as a proxy for the fossil fuel part of CO₂. The fossil fuel part of atmospheric CO₂ can be determined very well using ¹⁴C measurements (de Jong and Mook, 1982; Tans et al., 1979; Levin et al., 1980, 2008; Turnbull et al., 1323
2006). The method is however too laborious and expensive to obtain continuous high precision measurements with a temporal resolution of a few hours or less (Gamnitzer et al., 2006). When CO is calibrated regularly to $^{14}$CO$_2$ measurements, it can easily be used as a proxy for $^{14}$CO$_2$ and supply a continuous fossil fuel CO$_2$ record (Gamnitzer et al., 2006; Bakwin et al., 1998).

SF$_6$ is an anthropogenically produced molecule which is mainly used as an electrical insulator in high voltage applications. It is of interest because even though the current atmospheric background concentration is very low (<7 ppt) it is an extremely effective greenhouse gas due to its strong infrared absorption and a long atmospheric lifetime of about 3200 yr (Maiss and Brenninkmeijer, 1998). Its global warming potential is estimated to be about 23300 times that of CO$_2$ over a period of 100 years (IPCC, 2007). SF$_6$ is furthermore of interest because it can be used as an indicator for anthropogenic emissions (Turnbull et al., 2006; Rivier et al., 2006) since its sources (e.g. electricity plants) coincide with human activities.

High quality monitoring of the ambient mixing ratios of these five LLGHGs and tracers can greatly improve our knowledge of their regional sinks and sources and is needed to accurately determine their inter-annual variations. Several techniques currently exist to measure these five LLGHGs and tracers. CO$_2$ is mostly measured using a Non-Dispersive Infra-Red (NDIR) gas analyzer or with a Gas Chromatograph (GC). For both devices long term precisions of <0.1 ppm can be obtained. Extremely high measurement precision for CO$_2$ of about 0.003–0.01 ppm is reported with a LOFLO analyzer (Francey and Steele, 2003; WMO, 2005) which is basically a modified and improved commercial NDIR instrument. Analyzers for ambient measurements of CO$_2$ and CH$_4$ based on Cavity Ringdown Spectroscopy have recently become commercially available (Los Gatos Research Inc., CA, USA, Picarro, CA, USA) and their precisions are comparable to those of a GC or NDIR (<0.2 ppm for CO$_2$ and <1 ppb for CH$_4$). Currently, CH$_4$ is mostly measured with a GC using a Flame Ionization Detector (FID). With this technique, measurement precision of <2 ppb is obtainable. Recently, analyzers using quantum cascade laser technology have also become available for ambient
measurements of CO and N$_2$O with a suggested (LosGatos) precision of <0.3 ppb. At most stations however, N$_2$O is measured with a GC using an Electron Capture Detector (ECD) (WMO, 2001). Using an ECD, the obtainable precision is about <0.5 ppb. Conveniently, analysis of SF$_6$ can also be done with the same ECD (Maiss, 1992; Schmidt et al., 2001) and the obtained measurement precision is about 0.1 ppt.

Measuring ambient mixing ratios of CO with high precision at a continental site as Lutjewad can be challenging because of its large signal dynamics. CO mixing ratios can easily change by a factor of four from a clean background value of below 100 ppb up to 400 ppb (with polluted air masses) within short time. The corresponding variation of CO$_2$ is usually in the range of about 380 ppm to 430 ppm. This is in agreement with the finding that fossil fuel burning in the Netherlands on average delivers an amount of CO in the order of 1% of the amount of CO$_2$ (Meijer et al., 1996). Several techniques exist for measurements of ambient CO mixing ratios. Most of them are based upon using gas chromatography or optical spectroscopy. When using the first, the GC can be equipped with a mercury oxide reduction detector (Gros et al., 1999; Seiler et al., 1980), an ECD (Hurst et al., 1997) or with a FID (Rasmussen and Khalil, 1981). Measurement precision is in the order of 1–5 ppb for these methods at current atmospheric background levels. Other frequently used techniques for ambient CO measurements include: resonance fluorescence in the fourth positive band of CO (VURF) and Gas Filter Correlation Radiometry (GFC). The precision using VURF is about 1.5 ppb at an atmospheric mixing ratio of 100 ppb (Gerbig et al., 1999). GFC is a Non-Dispersive Infra-Red (NDIR) technique. A precision of about 1.4 ppb was reported after improvement of a commercial analyzer by Parris et al. (1994). Tunable diode laser spectroscopy (TDLS) offers a high sensitivity, a precision in the order of about 1 ppb, and response times of a few seconds but is still subjected to relatively high costs and requires well-trained operators. For a review on these measurement techniques see also Novelli et al. (1999) and references therein.

Considering all of the above and our quest to develop a high-precision and cost-effective instrument for continuously measuring the ambient mixing ratios of CO$_2$, CH$_4$, N$_2$O, SF$_6$ and CO.
N₂O, CO and SF₆, we decided to make use of gas chromatography. GC systems are very reliable and until now less difficult to operate and maintain than optical measurement systems and they require considerably less start-up costs than the laser-based technologies (WMO, 2001). Because of the fact that all species can be analyzed with either an ECD of FID only two detectors are needed. The instrument presented here is capable of measuring all five species practically simultaneously and under the same circumstances. Furthermore, the use of gas chromatography ensures that only a small sample is needed making this also an ideal facility for flask measurements. With the exception of maintenance work (e.g. replacement of carrier gas cylinders) the system reported here is designed to operate continuously without intervention of an operator needed, making this instrument highly suitable for unmanned and remote stations. In this paper we present a detailed description of the complete setup, followed by the procedures for calibration of the system’s response and the method for calculating the ambient mixing ratios. We will demonstrate that, after calibration against a suite of well-known WMO standards, only two working standards (references) for daily use are needed to determine the ambient mixing ratios of CO₂, CH₄, N₂O, CO and SF₆. Using a well-known target cylinder, we will show the long-term stability over more than 2 years. Finally, we will present mixing ratios as measured at our site Lutjewad in The Netherlands at 6°21′ E, 53°24′ N.

2 Technical description and analysis of components

2.1 Description of the system

Our measurement system is based upon a commercially available Agilent HP 6890N gas chromatograph (GC) which was modified to our purposes. For a detailed schematic diagram see Fig. 1. The basic principle is as follows: first, a sample loop is flushed with the sample air. Secondly, the sample is transported with a carrier gas and led through a chromatographic column were separation of the gases takes place. The
effectiveness of this separation is very sensitive to the gas flow, the temperature of the column and the type of column used. Finally, the individual components are analyzed by a detector. Two different detectors are used in this application: a Flame Ionization Detector (FID) for measuring CO$_2$, CH$_4$ and CO, and a micro Electron Capture Detector ($\mu$ECD) for measuring N$_2$O and SF$_6$. CO$_2$ and CO are catalytically converted to CH$_4$ prior to the analysis by flushing the gas with hydrogen through a nickel powder filled methanizer at 370°C.

The sample air is introduced into the system by entering a 16-port, electrically driven Valco valve (V7), which is controlled via the external events output connector of the GC, and flushed through three sample loops. For analysis of CO$_2$, CH$_4$ and CO two 10 mL sample loops are used: sample loop 3 is used for CO$_2$ and CH$_4$ and sample loop 2 is used for CO. A 15 mL sample loop (sample loop 1) is used for N$_2$O and SF$_6$. All sample loops are temperature stabilized at 60°C. Two mass flow controllers (MFC) (max. 500 mL min$^{-1}$, Bronkhorst, Ruurlo, The Netherlands) are used to stabilize the flow of the sample loops. They are set to 300 mL min$^{-1}$ for sample loop 1, and 450 mL min$^{-1}$ for sample loops 2 and 3. All sample loops are flushed for 0.55 min which represents at least eleven times their own volume of sample air.

Five columns are used for separating the individual components from the air sample. They are temperature stabilized at 72°C. CO$_2$ and CH$_4$ are separated using a 10 feet Haysep Q column (3/16 inch o.d., mesh 80/100, column 5). CO is separated with a 6 feet Porapack Q pre-column (1/8 inch o.d., mesh 80/100, column 3) and a 4 feet Molsieve 5Å analytical column (1/8 inch o.d., mesh 60/60, column 4). The function of the pre-column is to separate CO$_2$ from the sample and by (back)flushing it at the right time preventing it from entering and degrading the Molsieve column. Besides CO also CH$_4$ is separated by column 3, but since it is partly flushed away when the pre-column is backflushed, the CH$_4$ analysis is of too low quality to be used for our purposes. N$_2$O and SF$_6$ are separated from the air sample using two Haysep Q columns (3/16 inch o.d., mesh 80/100). One column is 4 feet long (column 1) and is configured as a pre-column and the second column is 6 feet long (column 2) and is used as the main
analytical column. The analytical column is connected to the µECD using a packed column adapter (Agilent part no. 19301-80530).

Following the separation of the air sample, the species are analyzed with the FID and the µECD. The temperatures of the detectors are stabilized at 250°C for the FID and 300°C for the µECD. The flame of the FID is fed by clean air (300 mL min⁻¹) and hydrogen (90 mL min⁻¹).

Nitrogen (quality 5.0) is used as carrier gas (and backflush gas in case of CO) for all species which are analyzed with the FID (CO₂, CH₄ and CO). It is led through a purifier (Aeronex 500k, Sigma-Aldrich, The Netherlands) in order to ensure stable baseline conditions. A mixture of Argon (95%) and Methane (5%) (quality 6.0, AirLiquide, Eindhoven, The Netherlands) is used as the carrier gas and backflush gas for both species which are analyzed with the µECD (N₂O and SF₆).

Five 6-port 2-way Valco valves (V1, V2, V3, V4 and V5), one 10-port 2-way Valco valve (V6) and four 2-port solenoid valves (V1.2, V8.1, V8.2 and V8.3) are used in the application. V1.2 is electrically connected with V1 and they are controlled simultaneously. The purpose of V1.2 is to prevent wasting of the relative costly Argon/Methane mixture when V1 is switched on. V8.1, V8.2, V8.3 are also electrically connected to each other and controlled simultaneously. V8.1 and V8.2 are used to close sample loop 3 in order to prevent the sample from leaking out (see process scheme). V8.3 is mounted between V7 and the MFCs as an extra prevention of potential leakage of the reference gases. Two valves (V5 and V6) are mounted on top of the GC for practical reasons due to limited space in the internal valve box of the GC. By placing them on top of the methanizer not only the tubing length is minimized but also the temperature of these valves is stabilized at about 70°C by using the waste heat of the methanizer.

All valves are controlled with Chemstation software (Agilent Technologies, v. B.01.01) using a sequence list containing all consecutive methods (i.e. measurement and analysis procedures). At the end of the list, the sequence is restarted by an external Delphi program. Chemstation is also used for the analysis of the chromatograms.
2.2 Process flow scheme

A detailed description of the process flow scheme is given in Fig. 2 (see also Fig. 1). Each run starts by switching V1 and V5 to “on”, and the four solenoid valves: V1.2, V8.1, V8.2 and V8.3 to “open”. All other valves are switched off. Now, all sample loops are flushed with sample air and all columns are flushed with the carrier gases. After 0.55 min V7 switches to a closed position in order to equilibrate the pressure in the sample loops with the room pressure. In this way, the sample loops contain virtually the same amount of molecules when either measuring ambient air samples or reference gases, provided the time between their consecutive measurements is kept short compared to atmospheric pressure changes. To prevent contamination with outside air due to backflow long capillary tubing is connected to the flushing outlets.

At 1.10 min 6-port, 2-way valve V4 and 10-port, 2-way valve V6 are switched on and the samples are flushed from sample loops 1 and 2 to the pre-columns. The sample from sample loop 3 is not flushed yet. To prevent the sample from diffusing out of this sample loop, V8.1 and V8.2 are closed. At 2.42 min V6 is switched off in order to backflush column 3. At 2.85 min V2 is switched on, and the sample leaving column 4 is led through the methanizer allowing CO to be converted to CH$_4$. The CH$_4$ in the sample air which elutes from the column prior to CO will also pass through the methanizer but this way we ensure the baseline to be undisturbed around the small CO peak. At 3.35 min V3 is switched on and the sample from sample loop 3 is injected into column 5 where CO$_2$ will be separated from the air sample. The FID is still connected to column 4 until V5 is switched off. This way, the FID first analyzes CO eluting from column 4 and sequentially analyzes CH$_4$ and CO$_2$ which will elute from column 5. At 3.98 min V5 is switched off and the FID is connected to column 5 just in time to detect CH$_4$, followed by CO$_2$. The exact switching time is chosen such that oxygen, which precedes CH$_4$, will not enter and degrade the methanizer by oxidizing the nickel catalyst powder. Meanwhile, at 3.80 min V1 was switched off in order to flush column 1 and allowing N$_2$O and SF$_6$ to be further separated from the sample in column 2. Following
the separation, they are measured by the µECD. Finally, at 6.48 min V2 and V3 return to their original (off) positions again, and V4 is switched off at 6.49 min. The total analytical procedure of one sample takes only 6.5 min, which makes it possible to do about 9 measurements of all 5 gases in one hour.

2.3 Chromatograms

The results of a typical run are shown in Figs. 3 and 4. The FID’s response is in pA, the response of the µECD is in Hz. Figure 3 shows the chromatograms from analysis with the FID. From left to the right (inset) first CH$_4$ and CO are seen, followed by a short spike which is caused by the switching of V5. This spike is closely followed by CH$_4$ and CO$_2$ (the largest peak). Figure 4 shows the output of the µECD. First a large O$_2$ peak is detected which is considered a by-product of the method. This peak is followed by the N$_2$O peak and finally the much smaller peak of SF$_6$. For the analysis of the peaks of CO$_2$, CH$_4$ and N$_2$O, integration of their areas is used. The peaks of SF$_6$ and CO are relatively wide compared to their heights. Therefore, they are more sensitive to small disturbances in the baseline and higher precision is obtained by using their peak heights for analysis. Typical peak characteristics are given in Table 1.

2.4 Additional remarks

Before entering the GC the ambient air has to be pre-dried. At our station we use Nafion membrane pre-dryers (MD 110-72-S, Perma Pure, Toms River, New Jersey) which remove up to 50% of the water vapor from the ambient sample. To freeze out the remaining water vapor, we use cold traps made of glass which effectively dry the air to a dewpoint of $-50^\circ$C and which are cleaned again automatically. The majority of the air which is not used is pumped back to the nafion to dry the new incoming air. For a detailed description of our drying system see Neubert et al. (2004).

Regular service is needed to supply the argon/methane mixture (about 95 L day$^{-1}$) and nitrogen (about 35 L day$^{-1}$), as well as water for the hydrogen generator (about
0.2 L day$^{-1}$). The usage of the reference cylinders is about 6.5 L day$^{-1}$ and for the target tank 2.7 L day$^{-1}$. For a 50 L reference cylinder this represents over 2 years of continuous measurements.

The efficiency of the methanizer needs to be tested on a regular basis. An interrupt of the hydrogen supply to the methanizer, e.g. by a FID-safety shutdown during power failure, can cause degradation of the methanizer if it is still at operation temperature. Ambient O$_2$ molecules diffuse into the FID outlet and oxidize the nickel powder, reducing the methanizer efficiency. Without action taken, recovery from 40% efficiency back to 100% can take several weeks. The efficiency of the methanizer can be tested by examining the response/concentration ratio of CO$_2$ to that of CH$_4$ for a well-known cylinder, since for a given cylinder the ratio of the mixing ratios of CO$_2$ to CH$_4$ is constant and thus should also be the ratio of their responses. In Sect. 4.1 we will give an example of this and the effect of the methanizer on the measurement precision.

Because of the relatively low ambient mixing ratio of N$_2$O and the high sensitivity of the µECD, N$_2$O can be applied as a very cheap and effective tool to check the whole system for any leakages (i.e. leaking room-air into the system). Even a very small leak will result in a significant increase in the response of the µECD when emitting some N$_2$O into the room. Since in most whipped cream cans N$_2$O is used as a propellant this can be used as a very cheap solution to test the system for any leakages.

### 3 Sampling strategy and calibration

Two reference cylinders with known mixing ratios are used to normalize the response of the detectors to an absolute scale. This scale is provided by the World Meteorological Organization (WMO). One reference cylinder (Ref$_{\text{high}}$) contains relatively high mixing ratios, the other one (Ref$_{\text{low}}$) contains relatively low mixing ratios. The mixing ratios are typically at the high- and low end of the current ambient mixing ratios. Both reference cylinders, as well as a third “unknown” target cylinder which is used for quality control, are periodically calibrated on the WMO scale using five primary calibration
cylinders provided by the National Oceanic and Atmospheric Administration/Earth Systems Research Laboratory (NOAA/ESRL, Boulder, Colorado, USA). They range from: 353 ppm to 426 ppm for CO₂, 1739 ppb to 2107 ppb for CH₄, 305 ppb to 326 ppb for N₂O, 89 ppb to 404 ppb for CO and 4 ppt to 8 ppt for SF₆.

During normal operation, the typical measurement sequence is deployed as:

Ref₁ high – S – S – S – Ref₂ low – S – S – S – Ref₁ high

in which “S” is a sample measurement. The responses of the two references are linearly interpolated in time to obtain reference values for each measured sample. One full analysis of either a sample or reference requires 6.5 min, hence every 26 min a reference standard is measured. This method largely reduces the errors caused by short-term variations (e.g. changes in ambient pressure) and still allows six sample measurements per hour. Three times a day, a sample analysis is substituted by a well-known target cylinder analysis for the purpose of quality control. Close observation of the target cylinder is key in detecting any potential problems (e.g. drift in one of the cylinders) at an early stage.

The concentration-response curves for CO₂, CH₄ and SF₆ are to a very good approximation linear. Therefore, the mixing ratio of a sample can simply be calculated by linear interpolation between the two references. The non-linear character of the concentration-response curves of CO and N₂O was significant, therefore we decided to use a second order polynomial function for their representation:

\[ C_x = \alpha R_x^2 + \beta R_x + \gamma \]  

Where \( C_x \) is the mixing ratio of a sample and \( R_x \) is the detector’s response for a sample measurement. and \( \alpha, \beta \) and \( \gamma \) are the fit parameters of the polynomial concentration-response curve. Since the response of the FID is very linear for the other species, the non-linearity of CO is most likely caused by its high dynamical range (over a factor of 4 difference between the two reference cylinders compared to 20–25% for CO₂ and CH₄), the response of the µECD is non-linear for SF₆ as well, but this is apparently not noticeable in the low-response range of SF₆.
Determining the coefficients $\alpha$, $\beta$ and $\gamma$ of Eq. (1) requires at least three references, preferably more. We determined the coefficients periodically using the five WMO standards, during the same exercise in which we (re)determined the values of our high and low reference cylinders and of our target.

However, for the daily maintenance of our calibration, we decided to use no more than two cylinders, just as in the cases of the linear responses. This strategy functions well, as the contribution of the 2nd-order term of the response curve is minor and has been relatively constant over the years that our system has been operational. Therefore, we can assume that the shape of the response curve does not change significantly over time, or its effect on the final mixing ratios is relatively small at the most. In this case, the information of the response curve Eq. (1), combined with the well-known mixing ratios of two references, yields the mixing ratios of a sample $C_x$ as follows:

$$C_x = C_1 + (C_2 - C_1) \frac{\alpha (R_x^2 - R_1^2) + \beta (R_x - R_1)}{\alpha (R_2^2 - R_1^2) + \beta (R_2 - R_1)}$$

(2)

Where $C_1$ and $C_2$ are the mixing ratios of the reference gases and $C_x$ is the mixing ratio of a sample. $R_1$ and $R_2$ are the response values corresponding to $C_1$ and $C_2$ and $R_x$ is the response of a sample measurement. $\alpha$ and $\beta$ are the fit parameters of the 2nd-order polynomial concentration-response curve, which are determined using the five WMO standards.

Applying Eq. (2), and assuming the shape of the concentration-response curve remains intact, necessitates only two well-known reference standards. However, although the shape of the response curve remains the same, the values of the fit parameters will vary over time because of changes in the response, especially for longer periods of several weeks or months for example due to reduced efficiency of the methanizer. Therefore we define: $\alpha'$ and $\beta'$ as the actual fit parameters at a certain time of a measurement during daily operation. We further introduce $r_{x,1,2}$ as the responses of
a sample or a reference standard at a certain time of a measurement during daily operation. $R_1$ and $R_2$ are now defined as the response values of two reference standards at the time of calibration (when the concentration-response curve and its fit parameters were determined with the five WMO standards). And $C_1$ and $C_2$ are their corresponding mixing ratios.

Assuming the shape of the response curve to be stable over time (i.e. the relative contribution of the 2nd-order term is constant), the change over time of the response (from $R$ to $r$) is then the result of a linear transformation only. The response of a reference (e.g.) during daily operation ($r$) and its response at the time of calibration ($R$) are then related as follows:

$$r_{1,2} = qR_{1,2} + k \rightarrow R_{1,2} = \frac{r_{1,2} - k}{q}$$

(3a)

Hence, the response at a certain time ($r$) can have an offset ($k$) compared to its original response ($R$) and can be multiplied with a certain sensitivity/response factor ($q$).

From Eq. (3a) we find for $k$:

$$k = r_2 - qR_2 = r_1 - qR_1$$

(3b)

And for $q$:

$$q = \frac{r_2 - r_1}{R_2 - R_1}$$

(3c)

Substituting Eqs. (3b) and (3c) in Eq. (1) we find:

$$\alpha' = \alpha \frac{q^2}{\left(\frac{r_2 - r_1}{R_2 - R_1}\right)^2}$$

(4)

And:

$$\beta' = \frac{\beta}{q} \frac{2\alpha k}{q^2} = \frac{\beta}{2\alpha} \left(\frac{r_1 - R_1(r_2 - r_1)}{R_2 - R_1}\right)$$

(5)
\( \alpha' \) and \( \beta' \) are the fit parameters now determined continuously by the measurement of the low and high reference cylinders. They are adapted to the linear transformation of the response. Through the linear extrapolation of the responses of the reference cylinders these coefficients are available for any point in time, and the mixing ratios for a given sample at a certain time and using only two reference cylinders, can thus be calculated as follows:

\[
C_x = C_1 + \left( C_2 - C_1 \right) \frac{\alpha' \left( r^2_x - r^2_1 \right) + \beta' \left( r_x - r_1 \right)}{\alpha' \left( r^2_2 - r^2_1 \right) + \beta' \left( r_2 - r_1 \right)}
\]

(6)

So far, we have (re)calibrated the response of Eq. (1) for \( \text{N}_2\text{O} \) and \( \text{CO} \) three times, and observed that the change of shape of the response is indeed below significance.

### 4 Results

#### 4.1 Measurement performance

The system as described in this paper has been operational at our atmospheric measurement station Lutjewad since May 2006. Since August 2007 two reference standards are available and calculation of the mixing ratios is performed as described above. A target cylinder has been measured since July 2007 every 7 h to validate the long-term reproducibility of the measurements.

As explained in Sect. 2.4 an interrupt of the hydrogen supply to the methanizer, if at operational temperature, can have an effect on the measurement performance of the GC. Figure 5 shows the efficiency of the methanizer from September to December 2007 after a power failure at the station on 5 September. The efficiency of the methanizer slowly increases from about 65% to 100% during a period of about two months. The mixing ratio of \( \text{CO}_2 \) as determined from the target cylinder is also shown. Although
scatter is seen at a methanizer efficiency of <90%, the effect on the measurement performance is still acceptable. When only one standard would be available, the accuracy would be off by about 0.8 ppm at a methanizer efficiency of about 65%.

Figure 6 shows the results for the target cylinder measurements for the period of July 2007 to September 2008. The mixing ratios of the target as determined by calibration with the WMO standards is illustrated by the lines drawn in the middle and is: 379.00 ppm for CO₂, 1859.9 ppb for CH₄, 149.2 ppb for CO, 314.3 ppb for N₂O and 6.06 ppt for SF₆. The lines above and below represent the upper and lower boundaries (1σ standard deviation) of the target based on the measurement precision. Our observed measurement precision was: ±0.06 ppm for CO₂, ±0.8 ppb for CH₄, ±1.7 ppb for CO, ±0.4 ppb for N₂O and ±0.10 ppt for SF₆. The average mixing ratios of the target cylinder and the 1σ standard deviations for this period were found to be: 379.01±0.06 ppm for CO₂, 1860.0±0.9 ppb for CH₄, 148.6±1.8 ppb for CO, 314.3±0.4 ppb for N₂O and 6.03±0.11 ppt for SF₆.

During the period of July 2007 to September 2008, various technical problems were encountered at the station, which is why there are some gaps in the dataset. For example: malfunction of our air-drying apparatus (resulting in wet air getting into the columns), failure of the air compressor which supplies the FID (causing oxidation of the methanizer) and several electrical power failures were encountered. Although the results in Fig. 6 show that accurate and reliable measurements with our GC are still possible under such harsh conditions, the situation was clearly sub-optimal. For a subset of Fig. 6, during optimal conditions we find the following “best case” 1σ standard deviations: ±0.04 ppm for CO₂, ±0.7 ppb for CH₄ and ±0.8 ppb for CO based on the data of the month December 2007, and ±0.3 ppb for N₂O (October and November 2007), and ±0.09 ppt for SF₆ (July and August 2007).

4.2 Ambient measurements

Figure 7 shows the results of the measurements of all five species in ambient samples from the total period of May 2006 to August 2008. The thick line in the plots is
a least squares regression fit on data indicated with the highlighted dots. This data represents non-polluted marine background values. In order to get the background mixing ratios we selected only day-time data for which the wind speed was $>3.5\text{ ms}^{-1}$ and the $^{222}$Radon ($^{222}\text{Rn}$) mixing ratio was $<0.33\text{ Bqm}^{-3}$. $^{222}\text{Rn}$ is a radioactive noble gas (its radioactive half-life time is 3.8 days) which is produced at a constant rate from $^{226}$Radium which is relatively uniformly distributed in all soils. It is measured at our station since September 2005. It can be used as an indicator for background mixing ratios because marine based air contains virtually no $^{222}\text{Rn}$ since water prevents the $^{222}\text{Rn}$ to emanate.

Our two reference standards were available only from August 2006 on, before this period the data was calculated with only one reference standard. This prevents us also to use a quadratic function to calculate the CO and $\text{N}_2\text{O}$ mixing ratios. Although the lack of a target cylinder for this period prevents us from knowledge about the reliability of the data, most of the data seems acceptable. $\text{N}_2\text{O}$ however, is probably about 1.5 ppb too low. Therefore, the $\text{N}_2\text{O}$ data before august 2006 is not used for determination of the background mixing ratio. The data for CO are more easily acceptable due to its much larger dynamical range.

Typical diurnal cycles are indicated by the high peaks for all species. For CO$_2$ the seasonal cycle representing the biospheric activity is clearly present. A seasonal cycle is also visible for CO and in much lesser extent (relatively) for CH$_4$, caused by a strong seasonality in their lifetimes. The average amplitudes of the seasonal cycles for the total period were estimated to be: 7 ppm for CO$_2$, 11 ppb for CH$_4$ and 35 ppb for CO. Average yearly trends were estimated to be: $+1.5\text{ ppm}$ for CO$_2$, $-7.5\text{ ppb}$ for CH$_4$, $-10\text{ ppb}$ for CO, $+1\text{ ppb}$ for $\text{N}_2\text{O}$ and $+0.3\text{ ppt}$ for SF$_6$.

The sudden decline in CO$_2$ mixing ratio at the beginning of June 2007 is remarkable. This is not an artefact as it is also reported at station Cabauw near Utrecht, in the centre of The Netherlands (A. Vermeulen, personal communication). A more detailed analysis of our measurements is to follow in another paper.
5 Conclusions

Our initiative was to develop a measurement system for measuring ambient mixing ratios of CO₂, CH₄, N₂O, CO and SF₆ with high precision and accuracy. We further desired the system to be: cost-efficient, reliable, easy to operate, autonomously operating, able to do several measurements per hour. Specifically, we wanted it to comply with the recommendations for atmospheric measurements as given by the World Meteorological Organization Global Atmosphere Watch (WMO, 2005, 2001). This organization gives recommendations for inter-laboratory comparability as follows: CO₂ ±0.1 ppm, CH₄ ±2 ppb, N₂O ±0.1 ppb, CO ±2 ppb and SF₆ ±0.02 ppt. The performance of our system thus has to be better than these values at least, in order to meet these objectives. Considering the observed 1σ standard deviations of ±0.04 ppm for CO₂, ±0.7 ppb for CH₄, ±0.3 ppb for N₂O, ±0.8 ppb for CO, and ±0.09 ppt for SF₆, our application meets the WMO recommendations for CO₂, CH₄ and CO. This is also achieved for the total period from July 2007 to August 2008 for which we found a 1σ standard deviations of ±0.06 ppm for CO₂, ±0.9 ppb for CH₄, ±0.4 ppb for N₂O, ±1.8 ppb for CO, and ±0.11 ppt for SF₆.

Concerning N₂O, an inter-laboratory comparability of 0.1 ppb is desired. However, the total uncertainty of our set primary WMO standards as provided by the NOAA is already 0.2 ppb. To our knowledge no device is currently capable of such high requirements. We therefore consider the estimated uncertainty of our N₂O measurements acceptable. Our obtained precisions are as low as those of the best other measurement systems currently available.

For SF₆ the WMO recommends an inter-laboratory (network) comparability of 0.02 ppt but consistency of scales (three scales are currently in use: NOAA, Univ. of Heidelberg, and SIO) has not yet met these targets. SF₆ is usually measured with a GC using an ECD or micro ECD and precisions using this technique are usually in the order of about 0.1 ppt, which we also meet.

We have demonstrated GC’s can ensure a high measurement precision and accu-
racy and that they have the advantage of being able to measure multiple components simultaneously.

We have also demonstrated that, together with a target cylinder for quality control, only two local reference cylinders are needed for daily routine. The facility is very cost effective: relatively low purchase costs, low in maintenance, few reference cylinders are needed and is designed to operate fully automatically. Our GC has proven its robustness by performing well under harsh conditions (i.e. several power failures). In total, the system is an ideal solution for measurements at remote and unmanned stations.

Fig. 1. Schematic design of the GC. The air sample enters the system through multivalve V7 and is stabilized with two Mass flow controllers. CO$_2$ and CH$_4$ are separated from the sample air using a Haysep Q column (column 5) and analyzed with the FID. CO is separated from the sample using a Porapack Q column (column 3) and a Molsieve 5A column (column 4) and is also analyzed by the FID. N$_2$O and SF$_6$ are separated with two Haysep Q columns (columns 1 and 2) and analyzed with the µECD. Valves V8.1, V8.2 and V8.3 are simultaneously controlled. V1.2 is simultaneously controlled with V1. All valves are drawn in their starting position.
Fig. 2. Process flow scheme indicating the switch time of all the valves. The starting position of V7 is determined prior to the run. V8 represents the three coupled solenoid valves V8\_1, V8\_2 and V8\_1, and V1 represents both V1 and solenoid valve V1\_2.
Fig. 3. Chromatogram of the FID with from left to right: CH$_4$ (1) and CO (2) followed by a spike caused by switching V5 and then CH$_4$ (3) and CO$_2$ (4).
Fig. 4. Chromatogram of the µECD. An oxygen peak (O, not used for analytical purposes) is followed by: N₂O (1) and SF₆ (2).
Fig. 5. Efficiency of the methanizer and the CO$_2$ mixing ratio of a target cylinder using one (open dots) or two reference cylinders. The accuracy and precision are strongly affected when only one reference cylinder is used.
**Fig. 6.** Target measurements of all measured species for the period of July 2007 to September 2008. The known mixing ratios of the target are illustrated by the lines in the middle and the lines above and below represent the upper and lower boundaries based on the measurement precision. The observed measurement precision was: ±0.06 ppm for CO$_2$, ±0.83 ppb for CH$_4$, ±1.7 ppb for CO, ±0.35 ppb for N$_2$O and ±0.10 ppt for SF$_6$ for the whole period.
Fig. 7. Ambient mixing ratios of CO₂, CH₄, N₂O, SF₆ and CO measured at Lutjewad, Groningen. Average yearly trends were estimated at: +1.5 ppm for CO₂, −8 ppb for CH₄, −10 ppb for CO, +1.0 ppb for N₂O and +0.3 ppt for SF₆.
