Abstract

Two types of temperature sensors are designed and tested, a thermocouple and a fine wire resistance thermometer. The intention of this study is to figure out which kind of measurement principle is in general more suited for atmospheric boundary layer meteorology with small RPA. The sensors are calibrated in a NIST traceable climate chamber and validated in flight against tower measurements, radiosondes and remote sensing. The sensors have a measurement range of at least \(-10\ldots50^\circ\text{C}\), an absolute RMS error of less than \(\pm 0.2\text{ K}\) which is stable over the lifetime of the sensors, and a resolution of about 0.01 K. Both devices are tested for typical errors like radiation error and adiabatic heating, as well as for their dynamic response. Spectral resolutions of up to approximately 10 Hz can be obtained with both sensors, which makes them suitable for turbulence measurements. Their low cost of less than 100 EUR in pure hardware is a major advantage for research with small RPA.

1 Introduction

In-situ observations in the atmosphere are of highest interest for weather nowcasting, forecasting, avionics and fundamental research. Measuring with aircraft has been a field of research for as long as aircraft exist (Neisser et al., 2002). A good overview of systems and strategies for airborne measurement of wind, temperature, and many other quantities is given in Lenschow et al. (1986), and other specialist literature (Wendisch and Brenguier, 2013; Emeis, 1995). An important aspect for the energy budget of the earth are the turbulent fluxes and turbulent structures of the atmospheric boundary layer (ABL) (Garratt, 1992). For the sounding of the atmosphere, numerous different methods are available nowadays: ground based measurements, tower measurements, vertical soundings with radiosondes or tethered balloons, aircraft and
helicopter measurements as well as remote sensing with radar\textsuperscript{1}, lidar\textsuperscript{2}, sodar\textsuperscript{3} and RASS\textsuperscript{4}, to mention only the most common instruments (Kaimal and Finnigan, 1994). Especially for the measurement of spatial averages of fluxes over heterogeneous terrain, ground-based, tower and radiosonde measurements are not suitable, because they are spot measurements which rely on the assumption of terrain homogeneity to calculate fluxes (Bange et al., 2006). Therefore, aircraft are much better suited instruments for these kinds of measurements. They can cover a wide area and perform in-situ measurements that do not rely on model assumptions of the atmosphere like e.g. remote sensing instruments do.

In contrast to stationary temperature measurements, sensors in airborne applications are facing specific requirements due to their operation on a moving platform in high stream velocities. While some issues like robustness or electromagnetic compatibility have to be addressed in the design process, other error sources like the heating of the sensor due to the conversion of kinetic energy to heat at the sensor surface have to be considered in the data analysis. The most commonly used temperature sensor for airborne research is the Rosemount Total Air Temperature Sensor (Rosemount, 1986). It was used in many meteorological campaigns with manned aircraft and systematically investigated. For example Friehe and Khelif (1992) tested the sensor against an NCAR K sensor and a modified Rosemount probe to find out about time responses, adiabatic heating effects and recovery factors. Inverarity (2000) found methods to correct the dynamic system of the Rosemount probe to measure more precise vertical profiles. Haman et al. (1997) designed a new sensor called “ultra-fast thermometer”, which design-wise makes it possible to measure in clouds without contamination of the measurement wire with cloud droplets. It uses a 2.5 µm platinum tungsten wire which

\textsuperscript{1} Radio Detection and Ranging \hfill \textsuperscript{2} Light Detection and Ranging \hfill \textsuperscript{3} Sound/Sonic Detection and Ranging \hfill \textsuperscript{4} Radio acoustic sounding system
makes it fast enough to make time response corrections obsolete. All these sensors are designed to be installed on manned aircraft, they are not optimised for small size or light weight.

Smaller sensors for airborne temperature measurement can be found in the context of radiosondes for vertical sounding of the atmosphere up to 30 km. These sondes need to be lightweight to be able to rise and be of low cost, because once released it is not guaranteed that the instrumentation can be recovered. Commercially available sondes work with thermistors or capacitive wire technology for temperature measurement. Typically, the wires used in these commercial sensors are coated or protected in some way to make them more robust at the cost of response time. Radiosondes are not suitable for turbulent flux measurements, because they only rise vertically. At ascent rates below 10 m s\(^{-1}\) and time constants \(\leq 1\) s, the blur in the allocation of the temperature reading to the corresponding altitude has a maximum size of 10 m. For their purpose of vertical soundings up to a few kilometers this is an acceptable error.

While meteorological measurements with manned aircraft and radiosondes are frequently performed, measurements with small unmanned systems are relatively new and not well established so far. Nevertheless, numerous different systems have been build up within the last decade and proved to produce valuable data (Martin et al., 2011; Reuder et al., 2009; Spiess et al., 2007; Dias et al., 2012; van den Kroonenberg et al., 2008). In general, the possibilities for meteorological measurements with small RPA are in between manned aircraft measurements and radiosonde soundings. Modern autopilots make it possible to fly predefined paths, even take off and land automatically if desired. Compared to manned aircraft their cruising speed is typically lower (20–30 m s\(^{-1}\)). The security standards are not as high as with manned aircraft, which in general makes them a more flexible tool, but the lack of harmonized rules in aviation authorities can cause additional limitations for flight permissions. Their application off-road makes it more likely that rough landings will damage a sensor. The space and payload capabilities are rather comparable to a radiosonde than a large research aircraft.
This work gives a description of two kinds of temperature sensors for the application on small unmanned aircraft for boundary layer meteorology. One sensor is based on a thermocouple, while the other one is a fine wire platinum resistance thermometer (FWPRT). Both sensors were calibrated and tested in a laboratory, before doing in-flight measurements and comparing the results with stationary measurements from a 99 m meteorological tower, as well as remote sensing measurements from a sodar and wind profiler. The goal is to be able to measure atmospheric temperature with a reasonable accuracy and sufficient resolution to also resolve turbulent fluctuations with both kind of sensors. By describing the advantages, disadvantages and problems in design and application, a guidance is given towards finding the best suitable sensor for individual RPA applications. It will be shown that these kind of sensors can be built on low cost and that typical errors for temperature measurement can be avoided or corrected.

2 Sensor design

2.1 Requirements

The temperature sensors described here are designed for the purpose of measuring mean temperature in the ABL, but also turbulent heat fluxes. As the target value of absolute accuracy in mean measurements, \( \pm 0.1 \) K is strived for. Although this accuracy is not critical for the evaluation of thermal stratification or turbulent transport, it can still be of relevance if complementary measurements with ground based, remote sensing or other airborne instruments are performed. A higher absolute accuracy than \( \pm 0.1 \) K is hardly achieved by commercial instruments, including the reference instrument in the used calibration chamber. Therefor this value is chosen as the target value for the new sensors.

Typical values for temperature fluctuations in different regimes are given for a field experiment in Wangara (Stull, 1988), stating that in a convective regime, fluctuations
σθ < 1 K are to be expected, and in the stable regime the fluctuations are much smaller (σθ < 10^{-2} K). From this example alone it can already be seen that it is important to measure temperature with a resolution and precision equal or better than 0.01 K.

Short response times are important to measure as far as possible into the inertial subrange of turbulence (Kolmogorov, 1941) to minimize the error in flux measurement introduced by neglecting small scale turbulence. In the boundaries of solid state temperature sensors that are robust enough for the application on small RPA, a response time smaller than 0.05 s (20 Hz temporal resolution) is considered a target value. Table 1 gives an overview over these requirements.

2.2 Interfaces and data collection

Both sensors that are described here were developed specifically for the application on a small UAV. The measuring system they are connected to is called AMOC (Airborne Meteorological Onboard Computer) and was developed in cooperation with the University of Applied Science Ostwestfalen-Lippe. The computer is based on two STM32 microcontrollers and interfaces to an Inertial Measurement Unit (IMU) and a GPS receiver. To be able to connect various other sensors, including the two temperature sensors described here, a 16 channel analog-digital-converter (ADS1258 by Texas Instruments) with 24 bit resolution (15-bit noise-free) and an input range of 0–5 V is integrated. All data is stored on a micro-SD card with a sampling rate of 100 Hz and is also transmitted to a groundstation computer for live observation at a rate of 1 Hz. In standard configuration, the whole measuring unit also includes a combined humidity and temperature probe (PCAP) and a five-hole probe (5HP) to measure the true airspeed vector (van den Kroonenberg et al., 2008). A block diagram of the system is given in Fig. 1.
2.3 Thermocouple

Measurements with a thermocouple are in first place always differential measurements between the measurement junction, where the thermocouple wires of unequal alloys are welded together, and the point where the thermoelectric voltage is amplified, or converted to a digital signal. Ideally this point should be in thermal equilibrium with the point where the thermocouple wires are physically connected to the electronics, in order not to measure temperature gradients in the measuring system. The big advantage of this method is the possibility to manufacture thin, long thermocouple wires to make point measurements of temperature in remote locations with a very short response time. To get the true absolute temperature, the differential measurement of the thermocouple always has to be added to a measurement of the cold junction temperature (Michalski et al., 1991). Therefore, a well-defined cold junction of the sensor is essential. A possibility to implicitly account for the cold junction temperature is to generate a voltage at the cold junction that corresponds to the thermoelectric voltage of the chosen thermocouple type for a temperature difference of the actual cold junction temperature. This voltage can then be added to the thermoelectric voltage of the thermocouple itself in an analog circuit, which after amplification and multiplication with the correct calibration coefficients gives an absolute temperature reading. An integrated circuit which takes care of this, is the LTK001 by Linear Technology. This chip is used in the design shown in Fig. 2.

For this setup to work, it is essential that the temperature sensor inside the LTK001 measures the true temperature of the cold junction. If there are gradients between soldering junction of the thermocouple wire and the chip, or if the temperature sensor inside the chip responds too slow to a sudden change in temperature, the temperature reading can be corrupted. To reduce these effects, the whole electronic components including the thermocouple connection were coated in insulating foam (Fig. 2).

Another method to get even more accurate absolute temperature readings from the thermocouple is a complementary filter. This means, the thermocouple signal is
high-pass filtered and added to a signal of a complementary temperature sensor that has a low-pass filter with the same cut-off frequency as applied for the high-pass of the thermocouple. The complementary sensor has to be a more stable and accurate temperature sensor that is also in the flow and responds just fast enough to sense the frequencies that are corrupted by wrong cold junction readings of the thermocouple. For this purpose a PT1000 was installed in close distance to the thermocouple on the RPA. The resistance of the PT1000 is measured with the PCAP01 signal processor by ACAM Messelelectron, which is also responsible for the measurement of a capacitive humidity sensor. This combined sensor is referred to as PCAP in this article. Figure 3 shows a sketch of all the sensors and temperatures involved in the current design. The thermocouple was built and tested with two different wire diameters (25 and 13 µm). The thermocouple type E (CHROMEGA® chromium nickel alloy and Constantan®) was chosen due to its chemical resistance and high sensitivity (60.9 µV K⁻¹).

For all measurement results for the thermocouple in the following, the complementary filtered signal is used. It showed the more trustworthy results compared to the internal cold-junction compensation of the LTK001. The amplification of the pure thermocouple voltage is chosen to achieve a sensitivity of 20 mV K⁻¹. Typical noise level for the whole measuring chain is 0.15 mV, so a resolution of 7.5 mK is realistic. The measuring range is adjusted to −10...240 °C. The precision and stability of the operational amplifiers that are used in the design is in the µV range, which is orders of magnitude better than the required precision.

2.4 Fine Wire Platinum Resistance Thermometer (FWPRT)

The FWPRT was designed based on Harrison and Pedder (2001). Few adaptations were done in the choice of operational amplifiers, and a printed circuit board was designed to reduce noise and size of the setup. The basic principle of the circuit is a linearized Wheatstone Bridge with current output, which is in the final step amplified and converted to a 0–5 V signal corresponding to approximately −10 to 50 °C measuring range. The measuring range can easily be adapted by the choice of the reference
resistor in the Wheatstone Bridge. One source of error that can already be addressed in the design process is self-heating of the fine wire. The bridge is designed and simulated to have a measuring current through the platinum wire of 0.6 mA. If we take into account that we have forced convection on the wire in flight, we can set up a power budget \( P_I = P_c \) which relates the power introduced by the measuring current \( P_I = R \cdot I^2 \) and the convective heat loss \( P_c = \alpha \cdot A \Delta T_{sh} \) to calculate the maximum self-heating of the wire:

\[
\Delta T_{sh} = \frac{R \cdot I^2}{\alpha \cdot A}
\]  

(1)

where \( \Delta T_{sh} \) is the temperature change due to self-heating, \( R = 100 \, \Omega \) is the resistance of the platinum wire, \( I = 0.6 \times 10^{-3} \, A \) is the measuring current, \( \alpha \) is the heat transfer coefficient calculated from the Nusselt number \( (0.39 + 0.51 \cdot Re^{0.5}, \text{with} \ Re = \text{Reynolds number}) \) and the molecular thermal conductivity of the air at a specific airstream velocity, and \( A = 3.7 \times 10^{-5} \, m^2 \) is the curved surface area of the wire (Foken, 1979). Figure 4 shows the theoretical self-heating for these values over a range of airspeeds calculated with Eq. (1). It can be seen that for this measuring current, self-heating effects are two orders of magnitude smaller than the goal for measurement accuracy and thus can be neglected.

The platinum wire of 25 and 13 µm respectively, is wrapped around the printed circuit board with minimum contact to the board itself, as can be seen in Fig. 5. It can also be seen that the wires are aligned in flight direction, which will theoretically minimize the effect of adiabatic heating of the wire. The resistance value of 100 Ω is a good compromise considering resolution, wire length and self-heating. Reducing wire length to get closer to point measurements will also reduce the resistance. A higher resistance gives better resolution, but the measuring current will necessarily increase, which leads to higher self-heating. The sensor has a sensitivity of 80 mV K\(^{-1}\) for a measuring range of \(-10\ldots50^\circ\text{C}\). The noise level is equivalent to the thermocouple circuit, so that a resolution of 1.8 mK is reached. Like in the thermocouple circuit, operational amplifiers were chosen that have a gain stability and precision that outranges the requirements.
3 Validation flights

3.1 The test site

An experiment was performed in September 2012 at the test field of the German National Meteorological Service (Deutscher Wetterdienst – DWD) close to Lindenberg, Germany. The site is located at 52.16143° N, 14.13071° E in North-East Germany in a heterogenous, but nearly flat terrain. Approximately 200 m from the take-off location for the RPA, a 99 m tower with meteorological instruments at 6 heights, including temperature, humidity, wind speed and wind direction measurements is installed. The tower is also equipped with sonic anemometers at two levels (50 and 80 m) for turbulence measurements. Besides the tower, there are also various remote sensing instruments installed on the test field. For comparison of temperature measurements, a sodar and a 482 MHz wind profiler can be taken into account, which both measure virtual temperature of the atmosphere along with wind speed and wind direction (Engelbart et al., 1999, 1996; Engelbart and Bange, 2002). Additionally, every six hours, a radiosonde is released in Lindenberg for soundings of temperature, humidity and wind.

3.2 The RPA system MASC

The platforms that are being used at the University of Tübingen to perform meteorological measurements are small RPA named MASC (Multi-purpose Airborne Sensor Carrier), which were developed in-house in cooperation with a local model aircraft builder. The MASC airframe as shown in Fig. 6 is an electrically powered motor glider aircraft of 3.00 m wingspan and a maximum take-off weight of 6 kg. In standard configuration with meteorological payload, the weight does not exceed 5.5 kg. A flight endurance of at least 40 min is possible at this weight with minimum battery load, which corresponds to a travelling distance of more than 50 km at a travelling speed of 22 m s\(^{-1}\). Tests in the windtunnel showed that the pusher motor does not effect the measurement system.
at the fuselage tip. Only very little flow disturbance was found due to the fuselage itself at typical airspeeds.

The aircraft are equipped with the autopilot ROCS (Research Onboard Computer System), which is developed at the Institute of Flight Mechanics and Control (IFR) at the University of Stuttgart (Haala et al., 2011). It was originally developed for photogrammetric applications and specifically adapted to the needs of meteorological observations. The autopilot makes it possible to fly pre-defined flight patterns automatically, guaranteeing a constant airspeed of 22–24 m s\(^{-1}\) and a level flight with deviations in altitude of less than 2 m in straight legs.

### 3.3 The experiment

The experiment was carried out in late summer 2012 from 21 September to 23 September. Two MASC systems were operated in this period. While at the first and third day of the experiment fair weather allowed a total number of 15 measurement flights with the system, the second day with more gusty winds and light rain was only used for test flights and technical improvements on the system. Several flights were done specifically to validate the temperature measurements of the two sensors described here. Two flights were performed flying squares with a size of 600 m around the tower at three heights where sensors are installed on the tower (60, 80 and 98 m). Another two flights were done at the time when radiosondes were released to measure vertical profiles between 60 and 500 m and compare the results. Figure 7 shows the flight paths for these two maneuvers. For comparison with the tower, the aircraft remained at each altitude for eight to ten minutes to have the same averaging period as the tower data. During straight and level flights, the standard deviation of barometric altitude is below 0.5 m. Including the bends, it is still below 2 m. Lateral deviations from the given track are within ±2 m. For the vertical profile, a constant climb rate of about two metres per second was chosen.

All temperature sensors involved were calibrated in a NIST (National Institute of Standards and Technology, USA) traceable climate chamber for a range of 15–50°C.
3.4 Results

The results of the comparison flights with the tower at three levels can be seen in Fig. 8. All flights show that the FWPRT measures a temperature that is constantly higher than the temperature measured at the tower. The two flights at the 21 September were done with exactly the same FWPRT sensor, on the 23rd another FWPRT sensor of the same type was used. The sensor used on the 23rd has a slightly bigger offset of about 0.6 K, compared to 0.4 K at the 21st. The PCAP sensor that is being used for filtering with the thermocouple systematically shows a lower measurement of about 0.2 K compared to the tower. These constant errors can be interpreted as calibration errors and are easily corrected by subtracting the measured offset. Analyzing all 10 min averages that were possible to extract from airborne measurements throughout the experiment, it was found that a mean error of −0.26 K with a standard deviation of 0.1 K for the PCAP sensor and a mean error of 0.46 K with a standard deviation of 0.09 K for the FWPRT was measured (see Fig. 9). The requirement of 0.1 K hence can be hold throughout the experiment, if a calibration offset between the sensors is subtracted once. The random errors include possible errors due to a bias between tower instrument height and controlled aircraft altitude, which can be up to 10 m. An error in altitude of this order at a lapse rate of 0.01 K m\(^{-1}\) will result in a temperature error of 0.1 K, which is in the range of the standard deviation. Another possible error source is the fact that the aircraft measurement is a spatial average, while the tower measurement is a point measurement. In laboratory conditions in a climate chamber, the sensors never exceed 0.1 K deviation with a quadratic fit over the whole calibration range. The experiment in Lindenberg could only cover a small range of temperatures. To find out if the error of the sensors are larger close to the edges of the calibration range or even beyond, more flight tests are needed.

Figures 10 and 11 show the result of the temperature sensors for two sequential vertical profiles at 11:00 UTC and 17:00 UTC respectively, in comparison to all other temperature measurements that are done at the test site in Lindenberg. For better comparison...
with the remote sensing systems, the RPA, radiosonde, and tower measurements are converted to virtual temperature according to the equations in Appendix A. Looking at all profiles, it can be seen that here as well, the FWPRT has an offset to the tower of about 0.5 K. The offset to the radiosonde and the wind profiler is slightly bigger. For the FWPRT, the lapse rate of virtual temperature is very well captured by the sensors and ascends and descends do not show remarkable hysteresis, which shows that the sensor’s time response is fast enough for the given climb rate. At 11:00 UTC, the radiosonde measures a higher lapse rate close to the ground which is neither captured by the tower, nor by the RPA. At 17:00 UTC, RPA, tower and radiosonde profiles have the same shape down to the ground. Most probably a local effect in the area where the radiosonde was released, which is approximately 3.5 km from the 99 m tower, is the reason for this difference in shape close to the ground between the measurements at 11:00 UTC. Thermocouple measurements (Fig. 11) show a strong hysteresis, which is due to the PCAP sensor, which is not able to adapt fast enough to temperature changes for the given climb rate and the thermocouple’s reference junction is not stable enough to make it possible to fill the gap to lower frequencies with pure thermocouple measurements.

4 Discussion of measurement errors

Two of the error sources that are most cited if it comes to temperature measurement with aircraft are radiation errors and errors due to adiabatic heating of the sensor element (Breitkopf and Kim, 1980; Foken, 1979; Daniels, 1968; Shannon and B.W., 2003). The measurement campaign in Lindenberg was also used to investigate these errors for the two sensor types described above. Condensation or icing, which both have fatal effects on measurements with fine wires, will not be considered.
4.1 Radiation error

To figure out the effect of radiation on the sensors, square pattern flights were chosen as well. In these flights, the aircraft was flying in all four main geographic directions. The flights were performed at late morning, between 10 and 11 a.m., with the sun in a south-easterly position (azimuth $\approx 135^\circ$, elevation $\approx 30^\circ$). The sensors are installed on the RPA in a way that for flights in North and East direction, sun was shining on the sensors, but in South and West direction, the sensors are shaded by the RPA itself. For FWPRT measurements, no significant offset between different flight directions could be found. For thermocouple measurements, an effect could be observed and is shown in Fig. 12 (left). It shows mean values for each leg in the square, colored according to the flight direction. For each square the temperature rises, but a constant offset between counterdirections of about 0.5 K is observed. The source for this offset is the PT1000 on the PCAP sensor. Repeating the same pattern with a shield around the PCAP sensor gives much better results with no significant offset between all directions (Fig. 12, right). The shield is made of a 2 cm diameter carbon tube covered with white adhesive film that completely covers the PCAP electronics. This result agrees with experiments performed in a wind tunnel using a light bulb as radiation source and exposing the sensor system with and without radiation shield. The fact that FWPRT measurements and also the pure thermocouple signal do not show this significant radiation errors shows that with fine wires of the diameter used in this system, at an airspeed of $20 \text{ m s}^{-1}$, hardly any radiation error is to be expected. In windtunnel experiments the radiation input was increased to a much higher level than in the test flights, radiating the sensors with up to 800 W m$^{-2}$, which corresponds to a hot summer day (see Fig. 13). The times when the radiation was switched on and off can clearly be seen in the PCAP measurements, while the FWPRT reacts with less than 0.2 K deviation from the windtunnel internal temperature trend.
4.2 Adiabatic heating

Adiabatic heating of a sensor occurs when the air is decelerated at the sensitive element of the measurement instrument. The kinetic energy of the air is transformed to heat. This heat leads to higher measurements compared to the static temperature. In theory, adiabatic heating can be described with the following adiabatic equation:

\[
T_s = r \cdot T_m \left( \frac{P_s}{P_t} \right)^{\kappa}
\]  

(2)

where \(T_s\) is the static temperature of the air, \(T_m\) the temperature measured by the sensor, \(P_s\) the static pressure, \(P_t\) the total pressure including the dynamic pressure at the sensor and \(\kappa = R_d/C_p \approx 0.28571\) the Poisson constant (ratio of the gas constant and the specific heat). Using this equation with boundary conditions of 293 K measured temperature, static pressure of 1000 hPa and an airspeed of 25 m s\(^{-1}\) leading to a total pressure of 1003.70 hPa, the measured temperature is \(\approx 0.3\) K higher than the true static temperature. In reality, the air is not only decelerated at the sensitive part of the sensor. The geometry of the sensor plays an important role for the effect of adiabatic heating. This is typically considered by the introduction of a recovery factor \(r\). The value of this recovery factor has to be evaluated in experiments (Breitkopf and Kim, 1980).

To see if the adiabatic heating effect does play a role at all for the sensor under investigation, the cross-correlation between temperature measurement and airspeed in a measurement flight at constant altitude can be calculated. Figure 14 shows the results for the FWPRT and the thermocouple respectively. Both maximum correlation coefficients are below 0.1. This is considered small enough to neglect errors of adiabatic heating in future experiments.
5 Spectral responses

To measure turbulent fluxes of heat, it is important to be able to resolve eddies as far as possible into the inertial subrange of turbulence. A spectral analysis of the measurements shows how high the temporal resolution of the sensor is, if the result is compared to the Kolmogorov law of locally isotropic turbulence in the inertial subrange (Kolmogorov, 1941). For the spectral analysis, the experiment in Lindenberg was not usable, due to internal noise caused by the telemetry system. This noise could be seen on all analog signals and was especially critical for thermocouple measurements due to the small voltage signal of this sensor. It could be clearly assigned to the telemetry, because it appeared at the same frequency as the downlink frequency. The issue was resolved and an experiment explicitly for spectral analysis was carried out close to Stuttgart, Germany. Again, box patterns like in Fig. 7 (left) were performed at a constant altitude of 150 m.

From the spectra in Fig. 15, it can be seen that for the 25 µm wires, the thermocouple seems to be able to resolve turbulent fluctuations of up to 20 Hz already, which is basically disturbed by electrical noise on higher frequencies, a problem that cannot be resolved by the use of thinner wires, only by an increased noise-free resolution of the thermocouple circuit. The FWPRT sensor of that wire diameter is already leaving the Kolmogorov slopes at 5 Hz. A possible reason is the greater length of the wire at this diameter compared to the thermocouple wire. Additionally to the power spectrum, the structure function according to Kolmogorov (1941) and Appendix B was calculated and is illustrated in Fig. 16. Here as well, the measurement of the FWPRT leaves the predicted slope much earlier than the thermocouple measurement.

6 Conclusions

In this study, two temperature sensors for airborne flux measurements in the atmospheric boundary layer were developed and tested extensively. Section 2 introduces
the requirements and explains the system design. The resolution and measuring range can already be guaranteed in the design process and is therefore met for both sensor types. Section 3 shows that each of the sensors has the ability to measure temperature within the desired accuracies, if calibration offsets are subtracted. Section 4 discussed the typical errors in airborne temperature measurements like radiation error and adiabatic heating and showed that for the given sensors these are small enough to be within the total accuracy of the sensors. Last, the spectral response of thermocouple and FWPRT were compared in Sect. 5. While the thermocouple in the current configuration is already able to resolve turbulent eddies up to 20 Hz and therefore meet the requirement, the spectral response of the FWPRT measurement attenuates much earlier (≈ 5 Hz). The slow response of the FWPRT is considered to be caused by the long wire length at 100Ω. Each sensor has certain advantages and disadvantages. While with thermocouple circuits it is most critical to provide a well-designed cold junction and an appropriate temperature measurement of the cold-junction temperature to achieve good total accuracies, the FWPRT with same diameter needs to have a well-designed wire-winding to get as close as possible to a point measurement and achieve correct temperature fluctuation measurements at high frequencies. In future designs of thermocouple circuits, more effort has to be taken into a well-measured cold-junction temperature to make it a standalone temperature sensor for both, good absolute accuracy and fast response. Alternatively, the result of the thermocouple measurement can also be complementary filtered with the FWPRT sensor. Future designs of the FWPRT sensor can be done with even smaller wire lengths and diameters to get closer to point measurements. It still needs to be proven that these are the reasons for the poor performance in measuring turbulent fluctuations. However, smaller diameters will lead to higher costs, because thinner platinum wire is more expensive and also more sensitive to rough conditions in flight. With the 25 µm wire, the sensor was never destroyed in flight, while tests with 13 µm did not withstand one rough landing.

Each of the sensors – as they were tested in this study – have pure hardware and manufacturing costs of less than 100 EUR. Therefore, these types of sensors are the
ideal equipment for fast temperature measurements aboard small RPA of type MASC or even smaller.

Appendix A

Virtual temperature

To calculate virtual temperature from each instrument under investigation, the relative humidity and barometric pressure measurements of the respective system is used. First the saturation water vapor $E$ for the measured static temperature $T$ (in °C) is calculated:

$$E = 6.107 \times 10^{\frac{7.45T}{235.0+T}} \text{hPa}$$

(A1)

The saturation water vapor $E$ is multiplied with the measured relative humidity value $\varphi$ to get the actual water vapor partial pressure $e$:

$$e = \frac{\varphi}{100\%} \cdot E$$

(A2)

Mixing ratio $m$ is calculated using the instrument’s barometric pressure measurement $p_s$ and water vapor partial pressure $e$:

$$m = 621.97 \cdot \frac{e}{p_s - e}$$

(A3)

Finally, virtual temperature $T_v$ is calculated from measured temperature $T$ and mixing ratio $m$:

$$T_v = (T + 273.15) \cdot \left(1 + \frac{0.61 \cdot m}{1000}\right)$$

(A4)

Virtual temperature is the temperature at which a dry parcel of air would have the same density as the measured moist parcel of air.
Appendix B

Structure function

The structure function is a statistic to show common variation. The eddy-size distribution of a turbulent flow in the inertial subrange, or the local structure of a turbulent flow was first and foremost quantified using the (auto-) structure function Kolmogorov (1941); Bange (2009).

\[
D_{\phi}(\tau) = \frac{1}{D-\tau} \int_{0}^{D-\tau} dt \left[ \phi(t + \tau) - \phi(t) \right]^2
\]

(B1)

where \(\tau\) is the lag or shift, \(\phi\) is the physical quantity, \(D\) is the total length of the time series and \(t\) is the time.

To simplify the interpretation of structure functions, they can be normalized by dividing by twice the variance of the time series:

\[
\frac{D_{\phi}}{2\sigma^2} = \begin{cases} 
0 & \text{: fully correlated} \\
1 & \text{: non-correlated} \\
2 & \text{: fully anti-correlated.}
\end{cases}
\]

(B2)

Acknowledgements. We would like to thank Frank Beyrich and Udo Rummel for the provision of data of all meteorological instruments at the meteorological observatory Lindenberg and their support on-site, Roland Kern for his excellent work on the aircraft, Walter Fichter, Florian Weimer and Alexander Joos at the IFR Stuttgart for their support with the autopilot system and Maximilian Ehrle for his great job as safety pilot. The measuring equipment would not have been ready to work without the help of Jens Dünnermann and Burkhard Wrenger from the University of Applied Sciences Ostwestfalen-Lippe.

Fig. 1. Block diagram of the meteorological measuring unit for small RPA of type MASC (Multipurpose Airborne Sensor Carrier), developed at the University of Tübingen. The computer is based on two STM32 microcontrollers and interfaces to an Inertial Measurement Unit (IMU) and a GPS receiver. To be able to connect various other sensors, including the two temperature sensors described here, a 16 channel analog-digital-converter (ADS1258 by Texas Instruments) with 24 bit resolution (15-bit noise-free) and an input range of 0-5 V is integrated. All data is stored on a micro-SD card with a sampling rate of 100 Hz and is also transmitted to a groundstation computer for live observation at a rate of 1 Hz. In standard configuration, the whole measuring unit also includes a combined humidity and temperature probe (PCAP) and a five-hole probe (5HP) to measure the true airspeed vector (van den Kroonenberg et al., 2008).

2.3 Thermocouple

Measurements with a thermocouple are in first place always differential measurements between the measurement junction, where the thermocouple wires of unequal alloys are welded together, and the point where the thermoelectric voltage is amplified, or converted to a digital signal. Ideally this point should be in thermal equilibrium with the point where the thermocouple wires are physically connected to the electronics, in order not to measure temperature gradients in the measuring system. The big advantage of this method is the possibility to manufacture thin, long thermocouple wires to make point measurements of temperature in remote locations with a very short response time. To get the true absolute temperature, the differential measurement of the thermocouple always has to be added to a measurement of the cold junction temperature (Michalski et al., 1991). Therefore, a well-defined cold junction of the sensor is essential. A possibility to implicitly account for the cold junction temperature is to generate a voltage at the cold junction that corresponds to the thermoelectric voltage of the chosen thermocouple type for a temperature difference of the actual cold junction temperature. This voltage can then be added to the thermoelectric voltage of the thermocouple itself in an analog circuit, which after amplification and multiplication with the correct calibration coefficients gives an absolute temperature reading. An integrated circuit which takes care of this, is the LTK001 by Linear Technology. This chip is used in the design shown in figure 2.

For this setup to work, it is essential that the temperature sensor inside the LTK001 measures the true temperature of the cold junction. If there are gradients between soldering junction of the thermocouple wire and the chip, or if the temperature sensor inside the chip responds too slow to a sudden change in temperature, the temperature reading can be corrupted. To reduce these effects, the whole electronic components including the thermocouple connection were coated in insulating foam (figure 2).

Another method to get even more accurate absolute temperature readings from the thermocouple is a complementary filter.
