Abstract

Here we present an experimental setup for water stable isotopes ($\delta^{18}$O and $\delta D$) continuous flow measurements. It is the first continuous flow laser spectroscopy system that is using Off-Axis Integrated Cavity Output Spectroscopy (OA-ICOS; analyzer manufactured by Los Gatos Research – LGR) in combination with an evaporation unit to continuously analyze sample from an ice core.

A Water Vapor Isotopic Standard Source (WVISS) calibration unit, manufactured by LGR, was modified to: (1) increase the temporal resolution by reducing the response time (2) enable measurements on several water standards, and (3) to reduce the influence from memory effects. While this setup was designed for the Continuous Flow Analysis (CFA) of ice cores, it can also continuously analyze other liquid or vapor sources.

The modified setup provides a shorter response time (~ 54 and 18 s for 2013 and 2014 setup, respectively) compared to the original WVISS unit (~ 62 s), which is an improvement in measurement resolution. Another improvement compared to the original WVISS is that the modified setup has a reduced memory effect.

Stability tests comparing the modified WVISS and WVISS setups were performed and Allan deviations ($\sigma_{\text{Allan}}$) were calculated to determine precision at different averaging times. For the 2013 modified setup the precision after integration times of $10^3$ s are 0.060 and 0.070 ‰ for $\delta^{18}$O and $\delta D$, respectively. For the WVISS setup the corresponding $\sigma_{\text{Allan}}$ values are 0.030, 0.060 and 0.043 ‰ for $\delta^{18}$O, $\delta D$ and $\delta^{17}$O, respectively. For the WVISS setup the precision is 0.035, 0.070 and 0.042 ‰ after $10^3$ s for $\delta^{18}$O, $\delta D$ and $\delta^{17}$O, respectively. Both the modified setups and WVISS setup are influenced by instrumental drift with $\delta^{18}$O being more drift sensitive than $\delta D$. The $\sigma_{\text{Allan}}$ values for $\delta^{18}$O of 0.30 and 0.18 ‰ for the modified (2013) and WVISS setup, respectively after averaging times of $10^4$ s (2.78 h).

The Isotopic Water Analyzer (IWA)-modified WVISS setup used during the 2013 Roosevelt Island Climate Evolution (RICE) ice core processing campaign achieved
high precision measurements, in particular for $\delta D$, with high temporal resolution for the upper part of the core, where a seasonally resolved isotopic signal is preserved.

1 Introduction

Water stable isotopes ($\delta^{18}O$ and $\delta D$, hereafter referred to as $\delta$) are powerful tracers for both present and past climate. The $\delta$-notation is a common way to represent the abundance of rare isotopes as a deviation from a reference ratio: $\delta^i = \frac{iR}{iR_{SMOW}} - 1$, where $iR$ and $iR_{SMOW}$ are the ratio between rare and abundant isotopes $^{18}O/^{16}O$, or $D/H$ in the sample and in VSMOW (Vienna Standard Mean Ocean Water), respectively.

Ice cores are valuable archives from which we can gain knowledge of past climate by investigating proxy records that are preserved in the ice or in entrapped gas bubbles, e.g. from water molecules, chemical impurities, particulates and methane gas (e.g. Petit et al., 1999; EPICA Community Members, 2004; WAIS Divide Project Members, 2013).

Proxy records provide important insights into Antarctic and Greenland's climate as observational data are limited to the most recent decades. Antarctic data are available from 1957 but with a bias towards coastal stations. Reliable satellite data providing extensive spatial coverage are available from 1979. Ice core proxy information offers a unique opportunity to extend the limited instrumental records (e.g. Steig et al., 2013; Thomas et al., 2013).

$\delta^{18}O$ and $\delta D$ have traditionally been used as a site temperature proxy in ice core records (Epstein and Mayeda, 1953; Dansgaard, 1964), but sea ice extent, atmospheric circulation, transportation pathways, changes in source region, as well as post-depositional effects (wind scour, diffusion, etc.) influence the $\delta$-signal (Jouzel et al., 1997; Masson-Delmotte et al., 2008; Küttel et al., 2012; Sinclair et al., 2013). Deuterium excess (d-excess) is a second-order proxy (d-excess = $\delta D - 8\cdot\delta^{18}O$; Craig, 1963; Dansgaard, 1964) commonly interpreted as describing relative humidity and temperature at
the moisture source region, as a result of the kinetic isotope effect during evaporation (Merlivat and Jouzel, 1979).

Laser spectrometry has made Continuous Flow Analysis (CFA) of δ in ice core melt streams possible (Gkinis et al., 2010; Maselli et al., 2013), replacing high resolution discrete measurements for delivering near-instrumental resolution (e.g. Rhodes et al., 2012; Sinclair et al., 2013) from ice cores. Here, we describe the design and performance of laser spectrometry δ-CFA systems used for analysis of the Roosevelt Island Climate Evolution (RICE) Antarctic ice core, retrieved from (79°21′46″ S, 161°42′3″ W, 560 m a.s.l.) an ice rise (Conway et al., 1999) situated at the north-eastern edge of the Ross Ice Shelf. With the objective to identify characteristic synoptic conditions in the Ross Sea region, the isotopic record’s correlation with sea ice extent, atmospheric circulation modes and local temperature will be investigated using reanalysis data (1979 to 2012). Establishing correlations and transfer functions between climate drivers and the ice core record for the recent past, where there are metrological data available will be important for the interpretation of the deeper part of the record.

Laser spectroscopy was first proven as a viable alternative to isotope-ratio mass spectrometry (IRMS) by Kerstel et al. (1999). The improvements within the field of commercially available laser absorption spectroscopy analyzers (Baer et al., 2002; Crosson et al., 2008; Berman et al., 2013; Steig et al., 2014) makes them suitable to analyze water vapor continuously to achieve high temporal resolution in-situ measurement series, within a range of research areas including atmospheric sciences (Johnson et al., 2011; Steen-Larsen et al., 2013), paleoclimate ice cores records (Gkinis et al., 2010; Steig et al., 2013; Maselli et al., 2013), ecology (Lee et al., 2007) and hydrology (Goebel and Lascano, 2012).

Over recent years vaporizing units that introduce vapor from standards to the absorption spectroscopy instruments have been developed to achieve reliable calibrations (Gkinis et al., 2010; Schmidt et al., 2010; Strum and Knohl, 2010; Steig et al., 2014). There are also commercially available calibration units; Water Vapor Standard Source (WVISS) manufactured by Los Gatos Research (LGR) and Standard Delivery Module
(SDM) by Picarro. The WVISS system vaporizes one standard using a self-aspirating nebulizer into a heated (75 °C) evaporation jar (Rambo et al., 2011); whereas the SDM uses a syringe-pump based system, which can switch between two standards (Tremoy et al., 2011).

During ice core CFA campaigns there are several simultaneous analyses, with at times conflicting requirements. CFA methane measurements require long uninterrupted periods of melting, due to large memory effect, whereas the 2013 IWA-custom-vaporizer δ measurements require frequent calibrations due to instrumental drift (Sect. 3.1). Therefore, the number of core sections that are melted without interruption (by stacking consecutive cores on top of one another) for calibration events is a compromise between the ideal time intervals of continuous melting for these different analytical methods.

Here, we present a new experimental setup with the aim (1) to increase the temporal resolution by reducing the response time, (2) enable measurements on several water standards, and (3) to reduce memory effects. The response time mainly depends on the size of evaporation chamber of the vaporizer. A short response time reduces the time required for completing calibration cycles and maximizes the resolution with which the δ-signal that is preserved in the ice is captured. Furthermore, a short response time limits the amount of sample that is lost at the transition to and from the ice core sample stream at the beginning and end of each core-stack measurement.

Aemisegger et al. (2012) showed that the L1115-i Picarro Cavity Ring-Down Spectroscopy (CRDS) analyzer has a longer response time compared to the LGR IWA by ~31 and ~22 s for δD and δ18O, respectively. Additionally, the signal for the L1115-i is biased by isotope-specific time lags (henceforth called lag bias), with δD having ~10 s longer response time than δ18O. A δ-signal without lag bias is important when calculating high-frequency d-excess values. The faster response time and lack of lag bias of our IWA-custom vaporizer setup allows us to explore the maximum extent to which the rapidly changing δ-signal preserved in an ice core can be resolved. The pumping rate of the cavity is higher for the IWA (500 to 800 mL min⁻¹) compared to the
L1115-i (25 mL min\(^{-1}\)) setup, which increases the turnover rate of the cavity, which is a contributing factor to the short response time of the IWA (Aemisegger et al., 2012).

The main system we describe (custom 2013) was developed and employed for the RICE CFA melting campaign (0 to 500 m) in 2013. It consists of a commercially available IWA from LGR, and a customized furnace and evaporation chamber, which was built and fitted inside a modified WVISS calibration unit. In addition to its function as a calibration unit, the custom vaporizer setup was used as a sample introduction system, where ice core melt stream is continuously vaporized and introduced to the IWA. A similar system (2014 custom setup) incorporating improvements was assembled for the 2014 RICE CFA melting campaign (500 to 761 m), and is described briefly.

The development of the custom \(\delta\)-CFA setup for ice cores was innovative, but similar setups exist at other research institutes (e.g. Gkinis et al., 2010). However, existing \(\delta\)-CFA systems for ice core analysis chose Picarro instruments. To our knowledge, we are the first research group to have developed a \(\delta\)-CFA setup for ice cores using Off-Axis Integrated Cavity Output Spectroscopy (OA-ICOS; Baer et al., 2002).

We perform a detailed characterization of the custom vaporizer setup and compare the performance of the custom and WVISS vaporizers. The stability and optimal calibration frequency for the setups were investigated by calculating the Allan deviation precision (Sect. 3.1). A definition of response times is introduced and response times were calculated for the custom and WVISS setup (Sect. 3.2). The response times were compared to a similar \(\delta\)-CFA ice core setup (Gkinis, 2014). The calibration method for the \(\delta\)-CFA data is presented in (Sect. 3.3) and the long-term stability of the IWA-custom vaporizer setup was evaluated using measurements on a control standard over a 35 day period (Sect. 3.4). Finally, the quality of the high resolution \(\delta\)-data from the RICE ice core are evaluated, by comparing the \(\delta\)-measurements with discrete samples (Sect. 3.5). The overall objective of this study was to establish an experimental CFA setup for ice cores that achieves \(\delta\)-measurements with high temporal resolution (sub-annual resolution) and describe its performance, operation and potential improvements.
2 Experimental

In this study, we use an absorption spectroscopy instrument based on OA-ICOS technology in combination with an evaporation unit to continuously analyze sample from an ice core or water standards during calibration. The absorption spectroscopy instrument is an Isotope Water Analyzer (IWA) manufactured by LGR.

The IWA-35EP analyzer uses a near-infrared, tunable diode laser, which scans over three nearby absorption peaks $\text{H}_2\text{O}$, $\text{H}_2\text{O}$, and $\text{HDO}$ located near the 1.4 µm wavelength. The instrument uses an OA-ICOS technique (Baer et al., 2002), where the laser is directed off-axis into an optical cavity. The semi-transparent cavity absorption cell has highly reflective mirrors, yielding an effective path length of several kilometers. The transmitted intensities are recorded by a photo detector. Laser spectroscopy analyzers are able to provide simultaneous measurements of $\delta^{18}\text{O}$, $\delta\text{D}$ and water vapor mixing ratios.

Sturm and Knohl (2010) reported on temperature sensitivity of the IWA. Recent IWA models have an Enhanced Performance (EP) feature, which improved the thermal control of the cavity by keeping the temperature of the cavity ($\sim 46.3^\circ\text{C}$) stable and elevated above the ambient temperature. Recent models also have the capability to measure $\delta^{17}\text{O}$, TIWA-45EP from LGR (Berman et al., 2013) and L2140-i from Picarro (Steig et al., 2014). Our IWA-35EP analyzer was updated in December 2013 to a TIWA-45EP analyzer, which added the capability of measuring $\delta^{17}\text{O}$ using a second tunable diode laser. The update of the analyzer enabled us to include $\delta^{17}\text{O}$ in our evaluation of the WVISS and the 2014 custom setup.

2.2 Evaporation/vapor introduction systems

We evaluate the performance of two water evaporation units, the WVISS calibration unit and the custom 2013 vaporizer setup. In addition to this we present preliminary data...
and results from the 2014 updated IWA-custom setup and new previously unpublished results from a CRDS L2140-i Picarro ice core setup (University of Copenhagen; Gkinis setup) with a custom made vaporizer (vaporizer and setup described in Gkinis et al., 2010; Steig et al., 2014).

2.2.1 WVISS system

The original WVISS unit (WVISS v.2 evaporation unit; manufactured December 2013) was setup to run a single water standard. A stream of water standard is continuously evaporated by the WVISS during calibration events. The WVISS unit consists of a heated (75 °C) 1.1 L-jar into which a nebulizer injects a constant stream of miniscule water droplets, which rapidly evaporate. For incoming dry air, the WVISS incorporates a built-in compressor and drier, but we chose to plumb to an external compressed dry air source to maximize stability and minimize noise and vibration in the laboratory. The dry air is split up into two flows inside the WVISS; one constant flow that goes through the nebulizer and the second constituting the majority of the dry air flow is regulated by a Mass Flow Controller (MFC) and is introduced to the evaporation jar. Tests of the WVISS unit were performed using external compressed dry air (< 20 ppm). When provided by the manufacturer, the nebulizer (Savillex, PFA C-flow 50 nebulizer) is set up to self-aspirate a flow of 50 µL min⁻¹ from a 0.5 L glass water bottle. We use a multi-port valve (C25-3186EMH, VICI), which enables us to use more than one water standard. Additional flow resistance introduced by the multi-port valve necessitated the use of a peristaltic pump (P2; MP², Elemental Scientific) to provide a more stable water flow to the evaporation chamber. The WVISS unit is described more in depth in Rambo et al. (2011) and Kurita et al. (2012).

The performance of a complete WVISS evaporation unit was also evaluated, using the TIWA-45EP LGR analyzer.
2.2.2 Experimental setup for water vapor isotope measurements

Building on the design of WVISS as a calibration unit supporting measurement of vapor samples, a key principle of our customized design was that both the ice core melt stream and isotopic standards passed through the same vaporization process. All changes to the WVISS involved readily available components that could easily be integrated within the WVISS shell and controlled with the IWA-WVISS system.

In the custom setup, we modified the following aspects of the setup: (1) volume of the evaporation chamber, (2) materials, (3) evaporation temperature, (4) introduction of the sample into the carrier gas, (5) reduction of travel distances of the samples. We will explain the rational and outcome of these changes in the following section.

Volume of the evaporation chamber

We reduced the internal volume of the WVISS evaporation chamber of 1.1 L to 40 mL in the 2013 custom vaporizer. The substantially smaller volume increases the turnover-rate and reduces the response time. This is particularly important when analyzing multiple standards and/or a rapidly changing continuous flow signal (e.g. from and ice core). The maximum resolution will be determined by the time it takes to replace the vapor volume in the evaporation chamber.

The evaporation chamber volume is less important for one-standard calibration setups (without the requirement of rapid volume exchange) as used for example to obtain real time measurements of atmospheric vapor for which the WVISS was designed (Rambo et al., 2011; Aemisegger et al., 2012).

Material

The WVISS setup has a Savilex sealed 1.1 L-jar evaporation chamber. For the 2013 setup we use borosilicate glass for the custom evaporation chamber. A cavity was milled within an aluminum block to hold the glass evaporation chamber in place and
conducts heat from the furnace efficiently into the evaporation chamber. Glass was chosen to permit to form the desired shape of the evaporation chamber.

**Evaporation temperature**

To achieve complete evaporation at higher vapor throughput rates, we increased the temperature of our custom furnace to \( \sim 170^\circ C \) compared to the WVISS, which operates at \( 75^\circ C \). The temperature of the custom furnace and WVISS evaporation jar is regulated using a PID regulated Omega temperature controller (CN7500).

**Introduction of the sample into the carrier gas**

Filtered compressed dry air (< 20 ppm) was used for evaporation of water sample flow and to transport the vapor to the IWA. Only a small portion of the total dry air flow goes through the nebulizer. The nebulizer injects a mixture of water and dry air into a glass evaporation chamber inside a customized furnace, where the sample water is instantaneously evaporated.

In the 2013 evaporation chamber, the moist air stream generated by the nebulizer (Fig. 1) and a line with dry air flow passes through the furnace parallel to each other in separate lines. These two gas streams are later merged, with the vapor line from the nebulizer being centered inside the dry air stream at the merger. Separating the two lines has the advantage that it provides a longer residence time in the furnace for the sample that is injected by the nebulizer. This ensures complete evaporation, if all of the dry air were to be introduced directly adjacent to the nebulizer the throughput rate of moist air can exceed the rate at which the dry air can be heated, causing inefficient and incomplete evaporation at high vapor throughput rate. The dry air line represents the majority of the total air flow (0 to 10 L min\(^{-1}\)) and the dry air flow is controlled by an Omega MFC.

After the vapor has left the furnace the internal pluming of the WVISS was used to transport the sample vapor to the analyzer. The water vapor concentration introduced
to the analyzer was $\sim 20\,000$ ppm. Excess vapor was vented to the atmosphere through the WVISS exhaust.

Further modifications were made in a 2014 IWA-custom setup, which uses two ceramic heating elements (122 mm, 250 W, and 230 V) to heat a stainless steel evaporation block to $165^\circ$C. The block is painted with high temperature black paint, to uniformly absorb radiant heat generated by the elements within a reflective cavity. The inner surface of the block is electro-polished. The same nebulizer is used as in the 2013 setup, and the mixing chamber is of similar dimensions. Dry air is pre-warmed in baffles and introduced adjacent to the nebulizer. Compared to the 2013 setup, a higher sample flow of $\sim 150\ \mu\text{L min}^{-1}$ matched with dry air flow to achieve $\sim 20,000$ ppm water vapor concentrations are used. Preliminary results from the 2014 setup are reported here, and differ only in the vaporizer construction, and in delivery of mixed vapor to the IWA directly through an open split, accomplished by a step in PFA tubing sizes, rather than through the WVISS plumbing system.

**Reduction of travel distance of the sample**

The 1/4” PFA tubing between the WVISS and the IWA, which provides the analyzer with sample, was kept short (59 cm) and a heat tape was wrapped around the tubing to prevent condensation and reduce adsorption to the tubing walls.

The sample flow from the ice core melthead separates the sample stream from the inner and outer parts of the core, allowing for clean chemical sampling from the inner section. For CFA $\delta$-measurements it is not necessary to have an ultra-clean sampling regime, but we recommend taking the sample stream from the inner line, to prevent blocking of the nebulizer. The $\delta$-measurement flow requires only 50 to $150\ \mu\text{L min}^{-1}$, and thus represents a minimal draw on the available sample volume. The melt rate was monitored to allow the association of each continuous ice core measurement with a depth.

A more detailed description of the melthead and the sealed debubbler (DB1, Fig. 2) used during the 2013 and 2014 RICE melting campaign is provided in Bigler et al. (2013).
et al. (2011). Air bubbles were introduced after DB1 to keep the sample flow in the tubing segmented. These air bubbles were later removed in DB2 located before the multi-port valve. The multi-port valve (C25-3186EMH, VICI) enables us to switch between sample from the ice core and multiple water standards (V2, Fig. 2 and Table 1). Switching between sample and calibration cycles was initiated through a control and data acquisition (DAQ) interface that was built in the LabVIEW software (National Instruments). Once the calibration cycle was initiated switches between water standards were automated. RS-232-to-usb cables were used to control and log positions of the valves (stored in calibration log files). A peristaltic pump (P2; MP<sup>2</sup>, Elemental Scientific) provides a constant water flow rate of 50 to 150 µL min<sup>-1</sup> to the nebulizer (Savillex, PFA C-flow 50 nebulizer, part nr. 800-1-005-01-00). PFA tubing was used for the water and vapor flows.

The IWA-custom vaporizer setup has proven to be reliable. The system performed without malfunction during the entire 2013 RICE melting campaign of 35 processing days.

3 Results and discussion

3.1 Signal stability (instrument drift)

Stability tests were performed to determine precision for different lengths of averaging times ($\tau_m$) and to quantify at which time scales instrumental drift affects the δ-signal (Allan, 1966; Werle, 2011). Allan deviation ($\sigma_{\text{Allan}}$, square root of Allan variance, Eq. 1; Werle, 2011) was calculated using several stability tests consisting of measurements on the (LHW) standard for extended time periods. Tests were performed on the 2013 and 2014 custom and the WVISS vaporizer at water vapor concentrations of
where $\tau_m$ is the averaging time and $\bar{\delta}_{j+1}$ and $\bar{\delta}_j$ are the mean values of neighboring time intervals $j$ and $j+1$.

Representative results from the 29 June 2013 are provided in Fig. 3. For $\delta^{18}$O two relatively stable periods can be seen separated by a transition period of instrumental drift between 11 and 13 h. We find that the instrumental drift is non-linear, and therefore challenging to correct for.

### 3.1.1 Custom vaporizer

The Allan deviation analysis for the custom vaporizer setup shows that precision increases with longer averaging times until the optimal averaging time is reached after $\sim 200$ and $\sim 600$ s with a precision of $\sim 0.04$ and $\sim 0.07$ ‰ for $\delta^{18}$O and $\delta$D, respectively (Figs. 4 and 5). For longer averaging instrumental drift becomes apparent. For this reason, averaging times beyond these values will have poorer precision.

After an averaging time of 60 s (approximately the response time of the whole ice core CFA setup) a precision of 0.05 and 0.15 ‰ is achieved for $\delta^{18}$O and $\delta$D, respectively. This level of precision is comparable to IRMS analyzes for $\delta^{18}$O (IRMS $\delta^{18}$O: 0.024 to 0.1 ‰) and outperforms IRMS analyzes for $\delta$D (IRMS $\delta$D: 0.5 to 1.0 ‰) (Strum and Knohl, 2010 and reference therein).

Due to competing requirements of various CFA analytical lines, calibrations were not run frequently enough during the 2013 RICE ice core processing campaign to avoid influence from instrumental drift on the CFA $\delta$-data. Calibrations were on average conducted every 2.4 h. Thus, the maximum temporal distance of any $\delta$-CFA measurement to a calibration event is $\sim 1.2$ h. The peak uncertainty is therefore given by the Allan deviation after 1.2 h, which is $\sim 0.17$ and $\sim 0.13$ ‰ for $\delta^{18}$O and $\delta$D, respectively (Figs. 4 and 5).
Analytical uncertainty in d-excess was estimated to range between 0.31 and 1.37 ‰ using Eq. (2). Peak uncertainty (1.37 ‰) occurs at the center point between calibrations (Figs. 4 and 5; 1.2 h ≈ 4320 s) and the minimum uncertainty (0.31 ‰) occurs near calibration points, within the optimal integration time for δ¹⁸O (200 s).

\[ \sigma_d = \left( (\sigma_{\delta D})^2 + (8 \cdot \sigma_{\delta^{18}O})^2 \right)^{1/2} \]  

(2)

For d-excess ice core measurements, a precision of ≤ 0.1 and ≤ 1.0 ‰ for δ¹⁸O and δD, respectively, is required (σd = 1.28 ‰; Masson-Delmotte et al., 2008). The δ¹⁸O measurements are more drift sensitive compared to δD data and are therefore the limiting factor for d-excess data. To achieve high-precision measurements for δ¹⁸O (< 0.1 ‰), a standard would have to be run for drift correction every ~ 1 h which is incompatible with CFA methane gas analyses.

To reduce the response time and the influence from instrumental drift, we are currently working towards a new setup, focusing on reducing the response time and the influence from instrumental drift even further. A reduced response time would allow us to run a drift standard during melting, only missing a small quantity of ice core analysis. Such an approach would accommodate competing requirements, such as frequent calibrations for isotope measurements and long periods of uninterrupted melting for methane measurements. Furthermore, if the instrumental drift is reduced, then less frequent calibrations will be required.

### 3.1.2 WVISS system

For the WVISS system the optimum averaging times are 700, 1000 and 1500 s with precisions of 0.04, 0.06 and 0.04 ‰ for δ¹⁸O, δD and δ¹⁷O, respectively.

The optimal averaging time is reached faster for the custom setup compared to the WVISS system indicating that the custom setup has higher precision compared to the WVISS during shorter integration times (e.g. 0 to 300 s for δ¹⁸O, Fig. 4). However, the
2013 custom setup is more susceptible to long-term drift beyond the optimal averaging time (Figs. 4 and 5).

The variability observed at long averaging times (beyond the optimum averaging time) shows the randomness of the drift, as drift occurs after different lengths of times for different tests (Figs. 4–6). Previous studies have shown results from singular tests (Gkinis et al., 2010; Sturm and Knohl, 2010; Aemisegger et al., 2012), averages from several tests (Steig et al., 2014) or from several tests but only for short integration times ($\leq 1000$ s; Maselli et al., 2013). Showing results from a suite of tests provides an improved estimate of the uncertainty of the results and the non-linear nature of the drift.

Aemisegger et al. (2012) conducted stability tests comparisons for averaging times from 0 to $10^4$ s (2.78 h). However, to investigate drift for longer averaging times, we consider averaging times up to $10^5$ s (27.8 h) and compare these results to the University of Copenhagen setup (Picarro instrument; L2140-i).

Our results show that the custom and IWA-WVISS setups are affected by instrumental drift. At averaging times of $10^4$ s the IWA-WVISS system have $\sigma_{\text{Allan}}$ values of 0.15, 0.06 and 0.10 ‰ for $\delta^{18}$O, $\delta$D and $\delta^{17}$O, respectively. For the 2013 custom setup the $\sigma_{\text{Allan}}$ values at $10^4$ s are and 0.3 and 0.25 ‰ for $\delta^{18}$O and $\delta$D, respectively.

For the 2013 modified setup the precision after integration times of $10^3$ s are 0.060 and 0.070 ‰ for $\delta^{18}$O and $\delta$D, respectively. For the WVISS setup the precision is 0.035, 0.070 and 0.042 ‰ after $10^3$ s for $\delta^{18}$O, $\delta$D and $\delta^{17}$O, respectively. Preliminary data from the updated 2014 IWA-custom setup (blue lines, Figs. 4–6) show that this system is less affected by instrumental drift compared to the 2013 setup; after integration times of $10^3$ s the 2014 system achieves $\sigma_{\text{Allan}}$ values of 0.030 ‰ for $\delta^{18}$O, 0.043 ‰ for $\delta^{17}$O, and 0.060 ‰ for $\delta$D.

Results from the University of Copenhagen setup show that the CRDS Picarro analyzer (L2140-i) and vaporizer achieves $\sigma_{\text{Allan}}$ values of 0.011 ‰ for $\delta^{18}$O, 0.010 ‰ for $\delta^{17}$O, and 0.048 ‰ for $\delta$D, after averaging times of $10^3$ s. The University of Copenhagen setup achieves higher precision and is less affected by drift compared to the
IWA-custom and IWA-WVISS setups. No instrumental drift can be detected for δ\(^{18}\)O and δ\(^{17}\)O for the L2140-i setup (Figs. 4 and 6). Therefore, more frequent measurements of drift correction standards will have to be performed for the IWA-custom setups in order to achieve the high precision measurements achieved by the L2140-i setup.

### 3.2 Response time

Isotopic step changes between water standards are used to calculate response times for the customized and the WVISS setup (Tables 3 and 4). The water vapor concentration was kept constant over the isotopic step change (\(\sim 20,000\) ppm). Cumulative distribution functions of the log normal distribution were fitted to the isotopic steps following Gkinis et al. (2010).

\[
\delta_{\text{fit}}(t) = \frac{K_1}{2} \left[ 1 + \text{erf} \left( \frac{\ln t - t_{\text{valve}}}{S\sqrt{2}} \right) \right] + K_2
\]

where \(t\) is the time and \(K_1, K_2, t_{\text{valve}}\) and \(S\) are constants which are estimated using least square optimization (LSO). The isotopic transition period, and thus the response time, was defined between the 5 and 95 % of the total isotopic step change (Eqs. 4 and 5). Beyond these limits, it becomes difficult to distinguish a step change from random signal noise.

\[
\Delta\delta_{\text{step}} = \delta_{\text{std1}} - \delta_{\text{std2}}
\]

\[
\delta\% = \frac{\delta_{\text{fit}} - \delta_{\text{std2}}}{\Delta\delta_{\text{step}}}
\]

where \(\Delta\delta_{\text{step}}\) is the size of the \(\delta\)-step between standard 1 (\(\delta_{\text{std1}}\)) and standard 2 (\(\delta_{\text{std2}}\)) and \(\delta\%\) is the percent change using \(\delta\)-signal from the fitted function in Eq. (3) \(\delta_{\text{fit}}\).

The response times for the customized setups are \(\sim 54\) and \(\sim 18\) s for the 2013 and 2014 custom setup, respectively. This is an improvement compared to the WVISS setup, which has response times of \(\sim 62\) s (Fig. 7, Tables 3 and 4).
The University of Copenhagen L2140-i (Picarro) analyzer and vaporizer unit setup achieves response times of 90 s for $\delta^{18}O$ and $\delta^{17}O$, and 94 s for and $\delta D$ (Fig. 7e and f, Tables 3 and 4). The IWA-custom setups (the 2014 version in particular) are more responsive compared to the IWA-WVISS and University of Copenhagen setup. Given the different design criteria of the system, it is plausible that the University of Copenhagen system is optimized for stability rather than response time, and there may be a trade-off between these two parameters.

Furthermore, the $\delta D$ isotopic step transition for the WVISS setup (Fig. 7d) is influenced by memory effects. A long tail is evident in the data before the final isotopic value is reached. The fit with the cumulative distribution function (Eq. 3) is poor while an exponential function improves the fit with the data. In contrast, the 2013 and 2014 custom vaporizer setup reaches the final stable isotopic value faster (Fig. 7b), which suggests it is less influenced by memory effects.

Figure 7 provides an example of a step change between two water standards RICE and ITASE for the custom 2013 and 2014 setups (Fig. 7a and b) and WVISS (Fig. 7c and d) setup. A step change of similar isotopic size is also provided for comparison from the Gkinis (2014) setup (Fig. 7e and f). The impulse response functions, the derivative of the isotopic fit ($\partial \delta_{fit}/\partial t$) for the setups, are shown in Fig. 7g and h.

The response time values presented in Table 3 are valid as a comparison between the WVISS and custom setup. However, the response times for the custom setup are not representative of the whole CFA system as the V2 valve is located downstream of the melter and debubbler (Fig. 2). Hence the attenuation of the $\delta$-signal prior to the valve is not taken into account. Gkinis et al. (2011) presented a method to calculate the attenuation for the CFA system using a power spectrum of the CFA data and a spectrum from discrete off-line measurements (ice pieces cut directly from the core) over the same depth interval as the CFA measurements.

Aemisegger et al. (2012) reported $\delta D$, $\delta^{18}O$, and water vapor mixing ratios response times of 4.5, 3, and 2.9 s, respectively for IWVA-WVISS setup. However, their isotopic step change is between one standard from the WVISS unit and the ambient air, which
provides the response times of the IWA. This way the evaporation chamber volume does not have to be replaced for the isotopic step to be complete. When an evaporation unit is used for switching between multiple standards and/or a changing CFA signal (e.g., from CFA sample stream from an ice core), it becomes critical to have a small evaporation chamber volume, as the vapor volume in the evaporation chamber needs to be replaced before the current signal can be analyzed.

The lag bias introduced by the IWA-vaporizer setups are negligible (for both the custom setups and WVISS setups). On average $\delta D$ is lagging $\delta^{18}O$ by 1 s (Table 3). A $\delta$-signal without lag bias enables the calculation of high-frequency d-excess values. For the WVISS and the IWA-custom 2014 setup we can also confirm there is no observable bias between $\delta^{18}O$ and $\delta^{17}O$, which is relevant for $^{17}O$-excess measurements (Tables 3 and 4). Furthermore, for the custom setups we find no relationship between the size of the isotopic step and the response time, nor the response time and the direction of the step (positive or negative).

We reduced the tubing length in our system for the vapor introduction to the analyzer compared to a typical atmospheric science setup, where it is necessary to have longer air intake lines. We hypothesize that our setup experiences less adsorption to tubing walls. This is important as adsorption can cause a bias between $\delta^{18}O$ and $\delta D$. The tubing between evaporation chamber and analyzer is only 59 cm, which required orientating the analyzer with the back towards the WVISS. Moreover, we applied heat tape to the tubing to reduce adsorption to tubing walls.

3.3 Calibration

The multiple water standard calibration cycle consists of four internal standards (Fig. 8); Lower Hutt milli-q water (LHW), Working Standard 1 (WS1), RICE (derived from RICE snow) and ITASE (derived from US-ITASE, West Antarctic snow). The values of the internal standards in relation to the VSMOW/SLAP scale were determined using discrete laser absorption spectroscopy measurements on the IWA-35EP analyzer (Table 1).
The CFA data import and processing is handled with MATLAB routines. A semi-automatic MATLAB script was set up for extracting standard measurements during calibrations and associating calibration events with the corresponding ice core melt section.

Water vapor generated from milli-q water (18 MΩ water) is supplied to the analyzer in between calibration and ice core melting periods, allowing us to easily distinguish between these events. We identify the start of the calibration measurement after the transition from milli-q to standard by finding the first time where the derivative of the δ CFA-measurement drops below a threshold. The time lag between the V2 valve and the analyzer is found using the calculated start time of the standard measurement and the time of the valve switch recorded in the calibration log file. Running milli-q water when the sample or standards are not analyzed also has the advantage that there is less risk of deposit build-up that can block the nebulizer.

Figure 8 shows an example of a typical section from δ-CFA processing of the RICE ice core. Three or four 1 m ice core sections were typically melted in between calibrations, by stacking consecutive cores on top of each other during melting. Normally the stack of cores takes up to 2.4 h between calibrations and one calibration cycle takes ~ 30 min.

The multiple water standard calibration cycle consists of three internal standards; WS1, RICE and ITASE. The values of the internal standards in relation to the VSMOW/SLAP scale are provided in Table 1. The isotope standards bracket the isotopic ice core record (Fig. 8).

Throughout our measurements the water vapor mixing ratio was kept at ~ 20 000 ppm in order to ensure data stability. To remove data that are affected by sudden changes in water mixing ratios (often caused by small air bubbles or drips) we used the following criteria. CFA data are removed when the difference between the 30 s moving average and 200 s moving average of water mixing ratio (ppm) exceeds 1 standard deviation (σ) of the 60 s moving average. In addition a cut-off limit of 15 000 ppm was implemented, which removes data that are stable but measured at mixing ratios that
deviate from our set measurement level (∼ 20 000 ppm). If an offset occurred from the
target water mixing ratio, the analyzer’s water vapor dependence is corrected accu-
rately if the magnitude of the offset in between calibrations is constant.

Each standard is analyzed for 500 s; the first 100 s and last 100 s of each standard
measurement are discarded, to conservatively avoid influence from memory effects.
Measurements shorter than 250 s are omitted. Figure 8 shows an example of the stan-
dards analyzed during a calibration cycle. Average values of 300 s were calculated for
each standard.

We follow the recommendation by the International Atomic and Energy Agency
(IAEA) of measuring multiple water standards for calibration (Kurita et al., 2012). We
fitted a multiport valve to switch between different water standards to the nebulizer to
perform calibrations. The RICE and ITASE standards are used for the two-point lin-
ear correction of the CFA-data. Correction slopes were calculated using the RICE and
ITASE standards directly before and directly after each melting period. The data are
normalized to the RICE standard to reduce the influence from instrument drift and
WS1 is used as a control standard. The calibration and normalization were linearly
time-weighted between the calibration events.

The average of correction slopes from calibrations throughout the RICE processing
campaign are: $\delta^{18}O = 0.941 \pm 0.0057$ (mean $\pm 1 \sigma$; $N = 324$) and $\delta D = 0.997 \pm 0.0043$.
Recent studies have obtained similar correction slopes ($\delta^{18}O = 0.941 \pm 0.008$ and
$\delta D = 0.994 \pm 0.003$; Aemisegger et al., 2012 and $\delta^{18}O = 0.946 \pm 0.005$ and $\delta D = 1.00 \pm 0.003$; Kurita et al., 2012) using an IWA-WVISS setup. It is important to use
a two-point calibration correction, as it is not feasible to calculate correction slopes
using a single standard corrections approach and any resulting deviation from the pre-
dominant slope would bias the calibration.

3.4 Long-term precision and accuracy

The RICE and ITASE standards are used for the two-point linear correction of the
$\delta$-CFA data and the RICE standard is also used for normalization to minimize in-
fluence from drift. Measurement on a control standard (WS1) was conducted as a check throughout the RICE processing campaign (35 days). The corrected CFA-measurements of the control standard provide a measure of the long-term precision and accuracy of the corrected δ-CFA data measured on the 2013 custom setup (Fig. 9). The data in Fig. 9 has been normalized using the VSMOW/SLAP value of the control standard (WS1; Table 1). The overall precision of the 177 standard measurements over the 35 days was 0.11 and 0.75 ‰ for δ¹⁸O and δD, respectively. The mean anomaly values of the corrected control standard values are −0.07 and −0.51 ‰ for δ¹⁸O and δD, respectively, and they provide an estimate of the overall accuracy of the measurements (black dashed line in Fig. 9). On the 16 June 2013 (day 167) problems were diagnosed with the vacuum pump for the IWA (N940, KNF), which appears to have affected the accuracy of δD (Fig. 9b).

3.5 High-resolution ice core record

To evaluate the quality of the calibration procedure, the corrected δ-CFA data was compared to discrete data (Fig. 10). Discrete measurements measured on an IWA-35EP (green dots) and DLT-100 analyzer (yellow dots) can be compared with δ-CFA data integrated over the discrete vial depth intervals (red dots). Figure 10 verifies the validity of the calibration procedure. Figure 11 provides a δD vs. δ¹⁸O biplot comparing both CFA and discrete data for a section of the RICE ice core (depth 133 to 144 m, section shown in Fig. 10). Figure 11 shows δD vs. δ¹⁸O applying a 41.3 s moving average (where 41.3 s is average sampling resolution for the discrete samples for this section, which corresponds to a depth resolution of 2.1 cm, assuming a melt rate of 3.0 cm min⁻¹) on the δ-CFA data (black dots), discrete data measured on a DLT-100 analyzer (green crosses) and discrete data measured on an IWA-EP35 analyzer (red crosses) and linear regression relationships for the three different data sets. We compare the slopes for discrete data measured on IWA-EP35 analyzer (8.21) and discrete data measured on DLT-100 analyzer (8.26) and
find that a linear best fit for the slopes is similar for the CFA data (8.18). The similarity of the slopes suggests that the uncorrected bias in the CFA data is negligible.

The discrete and CFA data for the 133 to 144 m section of the RICE ice core was investigated further, by creating histograms of the difference between the discrete data measured on the IWA-35EP analyzer and the CFA data. A difference was calculated for each discrete sample ($N = 215$). The CFA data averaged over the discrete vial depth intervals was calculated to make a direct comparison with the lower resolution discrete measurements.

The difference between the averaged CFA and discrete data was calculated to be $0.09 \pm 0.16 \permil$ and $0.70 \pm 1.07 \permil$ (mean $\pm 1\sigma$) for $\delta^{18}O$ and $\delta D$, respectively (Fig. 12). d-excess was calculated for the discrete and averaged CFA data, the difference being $-0.05 \pm 0.25 \permil$ (Fig. 12c).

4 Conclusions

This study outlines the process used to develop experimental CFA equipment for $\delta$-measurements with high temporal resolution (sub-annual) in the RICE ice cores, and describes the performance and operation of the equipment as well as potential improvements. The continuous flow laser system is the first using OA-ICOS in combination with a vaporizer unit to continuously analyze sample from an ice core. Direct measurements of water vapor of ambient atmosphere can also be performed.

Stability tests comparing the modified WVISS and the WVISS setups were performed and Allan deviations ($\sigma_{\text{Allan}}$) were calculated to determine precision at different averaging times. For the 2013 modified setup the $\sigma_{\text{Allan}}$ after integration times of $10^3$ s are 0.060 and 0.070 $\permil$ for $\delta^{18}O$ and $\delta D$, respectively. For the 2014 setup the corresponding $\sigma_{\text{Allan}}$ values are 0.030, 0.060 and 0.043 $\permil$ for $\delta^{18}O$, $\delta D$ and $\delta^{17}O$, respectively. For the WVISS setup the precision are 0.035, 0.070 and 0.042 $\permil$ after $10^3$ s for $\delta^{18}O$, $\delta D$ and $\delta^{17}O$, respectively. Both the modified and WVISS setup are
influenced by instrumental drift and $\delta^{18}\text{O}$ is more drift sensitive than $\delta\text{D}$ (Figs. 4 and 5).

The peak precision uncertainty for the 2013 custom CFA $\delta$-data is given by the Allan deviation after 1.2 h (center point between calibrations), which is $\sim 0.17\%$ and $\sim 0.13\%$ for $\delta^{18}\text{O}$ and $\delta\text{D}$, respectively (Figs. 4 and 5). Analytical uncertainty in $d$-excess was estimated to range between 0.31 and 1.37 $\%\delta$ using Eq. (2). 1.37 $\%\delta$ is the peak uncertainty (Figs. 4 and 5; $1.2\text{ h} = 4320\text{ s}$) and the minimum uncertainty (0.31 $\%\delta$) occurs near calibration points, within the optimal integration time for $\delta^{18}\text{O}$ (200 s).

Results from the University of Copenhagen setup shows that the CRDS Picarro analyzer (L2140-i) and vaporizer achieves $\sigma_{\text{Allan}}$ values of 0.011 $\%\delta$ for $\delta^{18}\text{O}$, 0.010 $\%\delta$ for $\delta^{17}\text{O}$, and 0.048 $\%\delta$ for $\delta\text{D}$, after averaging times of $10^3\text{ s}$. The University of Copenhagen setup outperforms the IWA-custom setups on the basis of precision (Figs. 4–6).

The mean response times for the customized setup are 54 and 18 s for 2013 and 2014 setup, respectively. This is an improvement compared to the WVISS setup, which has response times of 62 s. The University of Copenhagen L2140-i (Picarro) analyzer and vaporizer unit setup achieves response times of 90 s for $\delta^{18}\text{O}$ and $\delta^{17}\text{O}$, and 94 s for and $\delta\text{D}$ (Fig. 8e and f, Tables 3 and 4). The IWA-custom setups (the 2014 version in particular) are more responsive compared to the IWA-WVISS and University of Copenhagen setup and can therefore provide measurements with higher temporal resolution.

The two-point calibration process was evaluated by comparing the CFA data to discrete measurements. A $\delta\text{D}$ vs. $\delta^{18}\text{O}$ comparison plot (Fig. 11) revealed that that the discrete and CFA data have similar slopes: 8.18 for CFA data, and 8.21 and 8.26 for discrete data obtained from the IWA-35EP and DLT-100 measurements, respectively. This indicates that the uncorrected biased in the CFA data is negligible. The overall difference between CFA and IWA-35EP discrete measurements was $0.09 \pm 0.16\%\delta$ and $0.70 \pm 1.07\%\delta$ (mean $\pm 1\sigma$) for $\delta^{18}\text{O}$ and $\delta\text{D}$, respectively.

The IWA-custom vaporizer setups used during the 2013 and 2014 Roosevelt Island Climate Evolution (RICE) ice core processing campaign achieved high precision mea-
surements, in particular for $\delta D$, with high temporal (sub-annual) resolution for the upper part of the core.

**Acknowledgements.** We thank Cedric Douence, Andy Phillips for analyzing discrete samples on the DLT-100 LGR analyzer. Ed Hutchinson, Bruce Crothers, Steve Mawdesley and Rebecca Pyne for help with modification of the WVISS. Doug Baer and Manish Gupta (LGR) assisted with optimization discussions and provision of additional equipment. Stefanie Semper for LabVIEW programing.

The funding for the project was provided by the New Zealand Government through GNS Science (Global Change through Time Programme, GNS-540GCT12 and GNS-540GCT32) and Victoria University of Wellington (RDF-VUW-1103).

This work is a contribution to the Roosevelt Island Climate Evolution (RICE) Program, funded by national contributions from New Zealand, Australia, Denmark, Germany, Italy, the People’s Republic of China, Sweden, United Kingdom, and the United States of America. The main logistic support was provided by Antarctica New Zealand (K049) and the US Polar Program (I-209M).

Figure 1. Drawing of glass evaporation chamber. A moist air stream is generated from the nebulizer, merged with the MFC regulated dry air, is mixed at 170°C and subsequently flows out of the glass evaporation chamber to the IWA.
Figure 2. Flow chart of CFA IWA-custom vaporizer setup, where MH stands for melt head, V for valve, P for peristaltic pump and DB for debubbler. Blue lines represent the liquid part of the setup and the black lines represent the dry and moist air portion.
Figure 3. Shows results from a stability test using the 2013 custom vaporizer setup, measured over a 24 h period. 60 s moving averages of the 2 Hz-data is displayed. Deviation from mean value is shown for each point in (a) for δD and (b) for δ^{18}O. (c) shows water vapor concentration (ppm), and (d) shows analyzer cavity temperature (°C).
**Figure 4.** Allan deviation as a function of averaging time for δ^{18}O from stability tests of the custom vaporizer setups (2013 setup brown lines and 2014 setup blue lines), the WVISS setup (green line) and from the University of Copenhagen setup (Gkinis; black line). Average precision (1σ; standard deviation) for individual discrete samples measured on the IWA-35EP analyzer is shown as a black dashed horizontal line.
Figure 5. Allan deviation as a function of averaging time for $\delta D$ from stability tests of the custom vaporizer setups (2013 setup brown lines and 2014 setup blue lines), the WVISS setup (green line) and from the University of Copenhagen setup (Gkinis; black line). Average precision ($1\sigma$; standard deviation) for individual discrete samples measured on the IWA-35EP analyzer is shown as a black dashed horizontal line.
Figure 6. Allan deviation as a function of averaging time for $\delta^{17}O$ for stability tests on the WVISS setup (green lines), the 2014 custom setup (blue lines) and from the University of Copenhagen setup (Gkinis; black line).
Figure 7. (a–f) shows δ-CFA data (blue dots and green dots for the 2013 and 2014 custom setup, respectively), a LSO fitted curve (black line), 5 and 95% of change in the response time (RT) transition period (red line) for the custom setups (a and b) and WVISS setup (c and d) and the University of Copenhagen setup (Gkinis, 2014; e and f). (g, h) shows the impulse response function for the fit for the 2013 custom (black line), the 2014 custom (green line), the Gkinis (2014) (blue line), and the WVISS (red line) setup. The left column of plots (a, c, e and g) are for δ¹⁸O and the right column of plots (b, d, f and h) are for δD.
Figure 8. Example of raw-data from a melting session and calibration events from 25 June 2013. 1 m ice core sections were stacked on top each other during melting sessions. The ice core data are bracketed by calibration events. Water standards from the first calibration event are color marked. Yellow marking is for LHW standard, red for WS1, green for RICE, and blue for the ITASE water standard.
Figure 9. Normalized measurement of control standard (WS1) over 35 days. Raw data are shown as gray stars and corrected data as black dots (a) for $\delta^{18}O$ and (b) for $\delta D$. The corrected data has a standard deviation of 0.11 and 0.75 ‰ for $\delta^{18}O$ and $\delta D$, respectively. The mean corrected anomaly (black line) from the true WS1 standard value (thick red line) is $-0.07$ and $-0.51$ ‰ for $\delta^{18}O$ and $\delta D$, respectively.
Figure 10. Shows the 60 s moving average of the corrected 2hz δ-CFA data (black line), results from discrete measurements (green dots for measurements from the IWA-35EP analyzer and yellow dots for measurements on the DLT-100 analyzer), and δ-CFA data integrated over the discrete vial depth intervals (red dots); (a) for δ^{18}O, (b) for δD, and (c) for d-excess.
Figure 11. $\delta D$ vs. $\delta^{18}O$ for $41.3\,s$ moving average of the CFA data (black dots), discrete data measured on a DLT-100 analyzer (green crosses) and discrete data measured on a IWA-EP35 analyzer (red crosses) and linear regression relationships for the different data sets.
Figure 12. Histogram showing the difference between discrete and the CFA data; (a) for δ¹⁸O (b) for δD and (c) d-excess for depths from 133 to 144 m of the RICE ice core.
