Abstract

This paper shows the validation results of the satellite SO₂ observations from OMI (Ozone Monitoring Instrument) and OMPS (Ozone Mapping Profiler Suite) during the Icelandic Holuhraun fissure eruption in September 2014. The volcanic plume reached Finland on several days during the month of September. The SO₂ total columns from the Brewer direct sun (DS) measurements in Sodankylä (67.42° N, 26.59° E), northern Finland, are compared to the satellite data.

Challenging retrieval conditions at high latitudes (like large solar zenith angle, SZA) are considered in the comparison. The results show that the best agreement can be found for small SZAs, close-to-nadir satellite pixels, cloud fraction below 0.3 and small distance between the station and the centre of the pixel. Under good retrieval conditions, the difference between satellite data and Brewer measurements remains mostly below the uncertainty on the satellite SO₂ retrievals (up to about 2 DU at high latitudes).

The satellite products assuming a priori profile with SO₂ predominantly in the planetary boundary layer give total column values close to the ground-based data, suggesting that the volcanic SO₂ plume was located at particularly low altitudes. This is connected to the fact that this was a fissure eruption and most of the SO₂ was emitted into the troposphere.

The analysis of the SO₂ surface concentrations at four air quality stations in northern Finland supports the hypothesis that the volcanic plume coming from Iceland was located very close to the surface. The time evolution of the SO₂ concentrations peaks during the same days when large SO₂ total column values are measured by the Brewer in Sodankylä and enhanced SO₂ signal is visible over northern Finland from the satellite maps. This is an exceptional case because the SO₂ volcanic emission directly affected the air quality levels at surface in an otherwise pristine environment like northern Finland.

OMI and OMPS SO₂ retrievals from direct-broadcast measurements are validated for the first time in this paper.
1 Introduction

Atmospheric sulfur dioxide (SO$_2$) has significant impacts on the environment and climate. SO$_2$ is oxidised to form sulphate aerosols, which in turn participate to the stratospheric ozone destruction (Hofmann and Solomon, 1989) and cause Earth surface cooling (Charlson et al., 1990), by reflecting the incoming solar radiation. SO$_2$ is generated by natural sources (e.g., degassing and eruptions of volcanoes, sea spray) and anthropogenic sources (e.g., combustion processes). SO$_2$ is toxic when present in high concentrations at the surface and negatively affects human health.

SO$_2$ has been measured from space since the 1982 eruption of El Chichón (Krueger et al., 2008). This was the first time when SO$_2$ from satellite measurements could be determined. Those measurements were carried out by Total Ozone Mapping Spectrometer (TOMS), which had a limited SO$_2$ detection sensitivity, since the discrete measurement wavelengths were designed for total ozone retrieval (Krotkov et al., 2006). Since then, next-generation space-borne spectrometers like GOME (Global Ozone Monitoring Experiment) and GOME-2, SCIAMACHY (SCanning Imaging Absorption spectroMeter for Atmospheric CHartographY) and OMI (Ozone Monitoring Instrument) have shown greatly improved SO$_2$ detection sensitivity.

Currently, SO$_2$ from volcanic eruptions and degassing are routinely monitored using satellite data. For example, satellite measurements of volcanic SO$_2$ emissions can provide critical information for aviation hazard mitigation (Carn et al., 2008; Brenot et al., 2013). SO$_2$ has low background, making the volcanic SO$_2$ plumes clearly distinguishable even at long distance from the source. For example systems like SACS (Support to Aviation Control Service, http://sacs.aeronomie.be) use SO$_2$ as an indicator for volcanic activity and send email notifications when instrument specific SO$_2$ thresholds are exceeded (Brenot et al., 2013). Quality and timelines of satellite data products are essential for these kinds of services. Near real time (NRT) satellite products – typically available 3 h after the satellite overpass – are generally used for this purpose. Faster processing can be achieved if the so-called direct-broadcast (DB) data are used. This
is possible for example for NASA’s Terra, Aqua and Aura satellites as well as the recently launched Suomi National Polar Partnership (SNPP) spacecraft, which hosts the Ozone Mapping Profiler Suite (OMPS). The direct-broadcast concept is based on measuring and simultaneously sending the observations down to Earth for processing. The time needed for SO$_2$ processing is less than 15 minutes. However, this option is only available for specific locations on the Earth. Direct-broadcast data are received, for example, in Sodankylä (Finland) and SO$_2$ maps over central and northern Europe are available from SAMPO (Satellite measurements from Polar orbit, http://sampo.fmi.fi) service, which is built on the heritage of OMI Very Fast Delivery (Leppelmeier et al., 2006; Hassinen et al., 2008). This location is especially suitable for receiving DB data since several overpasses are available during one day.

The validation of volcanic SO$_2$ satellite products is challenging, as the ground-based measurements are not always available when volcanic eruptions occur. The first successful attempt to validate volcanic OMI SO$_2$ took place in 2008 after the Okmok volcanic eruption (Spinei et al., 2010). This was followed by an “opportunistic” validation study of Sarychev Peak volcanic eruption cloud, using a mobile ground-based instrument (Carn and Lopez, 2011). The conclusion of the latter study was that stationary ground-based measurements would provide better and more easily interpretable validation data. However, both studies show good agreement between ground-based and OMI SO$_2$ data. In these studies, about 3–5 OMI pixels were compared against ground-based observations.

GOME-2 SO$_2$ total columns have also been used for monitoring volcanic eruption (Rix et al., 2009) and validated, for example, during the eruption of the Eyjafjallajökull volcano (Iceland) in April and May 2010 using Brewer measurements (Rix et al., 2012). GOME-2 data agreed very well with the Brewer observations at Hohenpeissenberg (Germany), whereas the Brewer instrument at Valentia (Ireland) showed up to 50% higher SO$_2$ columns.

In this paper, both OMI and OMPS satellite observations are used to monitor the spatio-temporal evolution of the volcanic SO$_2$ cloud generated during the Holuhraun
(Iceland) fissure eruption in September 2014. Since the SO$_2$ plume reached northern Finland, this episode gives the opportunity to validate SO$_2$ satellite data against the Brewer SO$_2$ total columns available at Sodankylä ground-based station. Furthermore, the implications of such volcanic eruption on air quality in northern Finland are investigated, combining the time evolution of satellite observations and SO$_2$ concentrations at surface level. Section 2 describes the dataset used in the comparison. The validation results are presented and discussed in Sect. 3. The main findings of this work are summarised in Sect. 4.

2 Dataset

2.1 Satellite SO$_2$ products

In this study SO$_2$ total columns from OMI and OMPS satellite instruments are used to monitor the volcanic emissions during the Holuhraun fissure eruption in September 2014.

OMI is an UV-VIS spectrometer launched on-board EOS-Aura spacecraft in 2004 (Leviet et al., 2006). The nominal pixel size of OMI is 13 km $\times$ 24 km at nadir and 28 km $\times$ 150 km at the swath ends. The current local Equator crossing time is about 13:45. OMI covers the spectral range from 270 to 500 nm with a resolution of about 0.5 nm. The global coverage is achieved in two days. Since 2009 the so-called row-anomaly (see http://www.knmi.nl/omi/research/product/rowanomaly-background.php) has reduced the amount of valid pixels for volcanic clouds monitoring. Despite this anomaly, OMI data have been used in numerous studies for monitoring volcanic eruptions and anthropogenic pollution (e.g., Fioletov et al., 2011, 2013; McLinden et al., 2012).

OMPS is an UV spectrometer flying on-board Suomi National Polar-orbiting Partnership spacecraft since 2011 (Flynn et al., 2006). OMPS is a suite of three instruments: a nadir mapper, a nadir profiler and a limb profiler. In this paper the acronym OMPS
refers to the nadir mapper instrument only. OMPS measures backscattered UV radiance spectra in the 300–380 nm wavelength range (resolution of 1 nm) with daily global coverage. OMPS is build on a TOMS heritage and its pixel size (50 km × 50 km at nadir) is bigger than OMI, but it is still suitable for SO$_2$ monitoring, as shown by Yang et al. (2013).

In order to obtain the total SO$_2$ columns from OMI and OMPS measurements, the same retrieval techniques are applied to both instruments and four different SO$_2$ total column estimates are provided, based on different assumptions of the SO$_2$ vertical profile. The assumed SO$_2$ profile shape is represented by its center of mass altitude (CMA), defining the vertical region where SO$_2$ is predominantly distributed. The products are (1) Planetary Boundary Layer (PBL) SO$_2$ column, corresponding to CMA of 0.9 km, (2) Lower tropospheric (TRL) SO$_2$ column, corresponding to CMA of 2.5 km, (4) Upper tropospheric and Stratospheric (STL) SO$_2$ column, corresponding to CMA of 17 km. The TRL, TRM and STL data products are processed using the Linear Fit (LF) algorithm designed for large volcanic SO$_2$ loads (Yang et al., 2007) and the PBL product is retrieved using the Band Residual Difference (BRD) algorithm (Krotkov et al., 2006, 2008). Both BRD and LF algorithms take the residual after the ozone retrieval (SO$_2$ assumed zero) as an input. In the current OMI PBL standard product, the BRD algorithm has been replaced with the recently developed Principal Component Analysis (PCA) algorithm (Li et al., 2013). The SO$_2$ retrieval algorithm information are summarised in Table 1.

In this study, OMI SO$_2$ standard product (SP) (available at http://mirador.gsfc.nasa.gov) and the OMI and OMPS direct-broadcast data products are used. The direct-broadcast data are received through the ground-based antennas located in Sodankylä, northern Finland. OMI and OMPS DB images are available from SAMPO (http://sampo.fmi.fi) website. Note that OMPS operational data are not yet distributed and they are not included in this study. Thus, the OMPS data correspond here to the direct-broadcast dataset, while OMI data are available as both standard product and direct-broadcast datasets.
The accuracy and precision of the retrieved SO$_2$ column depend on various factors like CMA, SO$_2$ column amount, measurement geometry, ozone slant column density and solar zenith angle. For OMI, the SO$_2$ README file v.1.2.0 (available on line at http://so2.gsfc.nasa.gov/Documentation/OMSO2Readme_V120_20140926.htm) discusses the error estimates of the standard products. One way to study the error estimates is to study SO$_2$ retrievals in a pristine, presumably SO$_2$-free location, like Equatorial Pacific. A recent study by Li et al. (2013) reports standard deviations (STDs) of about 0.5 DU and 1 DU for PBL PCA and PBL BRD algorithms, respectively. For TRL, TRM and STL algorithms the STDs are reported in the README file as 0.7 DU, 0.3 DU and 0.2 DU, respectively.

A similar study can be conducted at high latitudes too. The results of this analysis are shown in Sect. 3.

2.2 Ground-based measurements

The SO$_2$ total columns from the Brewer spectrophotometer MK II #037 located in Sodankylä (67.42° N, 26.59° E), Finland, are compared to the satellite retrievals. The SO$_2$ total columns are calculated from direct solar (DS) irradiances at the wavelengths of 306.3, 316.8 and 320.1 nm using the total ozone retrievals derived from the same instrument. The normal SO$_2$ values in Sodankylä are close to zero with an estimated detection limit of about 1 DU, similarly to the values reported by Rix et al. (2012) for Hohenpeissenberg. Georgoulias et al. (2009) found that the average SO$_2$ column values at most of the European Brewer sites are typically less than about 1 DU. Higher values of column SO$_2$ have been measured by Brewer instruments at sites affected by volcanic eruptions. For example, Fioletov et al. (1998) reported observations of column SO$_2$ amounts of more than 20 DU over Kagoshima as related to volcanic activity.

For this study, the atmospheric composition measurements were also available at four ground level air quality monitoring stations located in northern Finland: Sammallunturi (67.98° N, 24.12° E, 566 m), Kevo (69.76° N, 27.02° E, 107 m), Raja-Jooseppi (68.48° N, 28.30° E, 262 m), Oulanka (66.32° N, 29.42° E, 310 m). These remote rural-
background monitoring sites have no significant SO\textsubscript{2} emission sources in the vicinity, but are occasionally affected by the industrial SO\textsubscript{2} emissions from the Kola Peninsula, Russia. The surface SO\textsubscript{2} concentrations were measured using online trace level gas analysers based on the ultraviolet fluorescence method (i.e. European reference method). Measurement height is 4–5 m. The concentrations are recorded at 1 min intervals and, in this study, the hourly average values are used.

3 Results and discussion

3.1 Timeline of Holuhraun eruption

On 16 August 2014 the first indications of increasing seismic activity close to the Bárðarbunga (64.60\degree N, −17.50\degree E) volcano were reported by the Icelandic Met Office (see http://en.vedur.is/earthquakes-and-volcanism/articles/nr/2947). On 31 August the eruption started in the Holuhraun fissure, located northeast from Bárðarbunga. It was a continuous effusive fissure eruption, without explosive activity.

Figure 1 shows the time evolution of the OMI TRL SO\textsubscript{2} maps over northern Europe during selected days after the volcanic eruption. The first enhanced SO\textsubscript{2} signal from satellite observations was detected over Iceland on 1 September (Fig. 1 – top left panel). During the next days the SO\textsubscript{2} plume moved eastward toward Scandinavia (Fig. 1 – top centre panel). According to the satellite observations, the plume reached the first time northern Finland on 5 September (Fig. 1, top right panel). After that, high SO\textsubscript{2} total column values over large areas in northern Finland were observed on 10, 27 and 29 September (Fig. 1, bottom panels). At the time of writing this paper, the Holuhraun eruption is still ongoing. This validation study has been limited to the month of September, in order to avoid extremely challenging observing conditions for the satellite retrievals occurring during fall-winter. In fact, the sensitivity of the satellite measurements to atmospheric trace gases in the lower troposphere is significantly re-
duced for large solar and/or viewing angles or when the field of views are affected by the clouds.

3.2 Comparison between satellite and ground-based SO$_2$ total columns

SO$_2$ total columns from Brewer observations in Sodankylä during six days on September 2014 are presented in Fig. 2 (black dots). Only selected days with sufficiently continuous Brewer DS measurements are considered. For comparison, SO$_2$ total columns from both OMI SP and OMPS overpasses over Sodankylä are shown in Fig. 2. OMI DB SO$_2$ data are also available but they are not included in Fig. 2 since several orbits were missing on the second half of September due to processing anomaly. For completeness, the OMI DB data (when available) are reported in Table 2 and their agreement with the ground-based observations will be discussed later in this section. The satellite datasets include four SO$_2$ products sensitive to different altitude regions as described in Sect. 2. In OMI SP, the PBL data are processed using both the PCA (blue circles in Fig. 2) and the BRD (pink stars in Fig. 2) algorithms. OMI and OMPS DB datasets are processed using the BRD algorithm. An overview of the satellite overpasses over Sodankylä (during the same days shown in Fig. 2) are presented in Table 2, together with the Brewer SO$_2$ observations closest (within 30 min) to the satellite overpass time.

The best agreement between ground-based and satellite SO$_2$ total columns is generally found for the PBL product (blue circles and crosses, and pink stars in Fig. 2), which corresponds to the SO$_2$ total column most appropriate for the planetary boundary layer levels. This suggests that the volcanic plume might be located close to the surface. On the second half of September, the agreement is weaker because of the challenging retrieval conditions (e.g., high SZA and cloudy conditions). In general, for high-latitudes cloud-free observation conditions, the PBL products are expected to underestimate SO$_2$, since much smaller solar and vertical zenith angles are assumed in the retrievals. Overall, OMI seems to be more sensitive to the signal at low-altitudes than OMPS. The results of the comparison are analysed day-by-day below.
5 September 2014. The volcanic plume reaching Finland produces SO$_2$ total column values up to about 6 DU in Sodankylä as observed from the Brewer measurements. The best agreement with the SO$_2$ satellite products is achieved for OMI PBL data from the BRD algorithm. OMI SO$_2$ total column at 09:57 is 2.49 DU for the SP BRD dataset and 2.85 DU for the DB dataset, and the closest Brewer measurement is 3.7 DU. This overpass corresponds to favourable measuring conditions i.e., small OMI pixel (number 16), small distance between the pixel centre and the ground-based station (7.7 km), relatively small SZA (60.6°) and cloud fraction CF (0.21) smaller than 0.3.

6 September 2014. Only OMI data are available because OMPS observations on Saturdays are dedicated to high resolution mode. One clear-sky overpass from OMI is available. Also in this case the satellite PBL product gives the best agreement with the corresponding Brewer retrieval. PCA and BRD algorithms give very similar results: SO$_2$ total column at 09:03 is 2.59 DU from BRD algorithm and 2.79 DU for PCA, while the closest Brewer measurement gives 4.4 DU. Also OMI PBL SO$_2$ total column value (3.86 DU) from direct broadcast is close to the ground-based observations. As on 5 September, this overpass corresponds to relatively good observation conditions (pixel number = 6, distance = 8 km, CF = 0.24 and SZA = 62.1°).

10 September 2014. Two overpasses are available from both OMI and OMPS, but only one OMI overpass is under clear-sky conditions. Brewer data show again their best agreement with the PBL products. OMI SO$_2$ total column at 10:16 is 4.4 DU for PCA, 3.31 DU for BRD and 2.73 DU for the direct-broadcast BRD dataset. The closest Brewer observation gives SO$_2$ total column value of 2.6 DU. OMPS data are very similar to OMI except for the PBL products.

27 September 2014. From now on, the satellite overpasses correspond to SZA about 70° or larger. This makes the retrieval from satellite more difficult. Only OMI overpasses are available and only one is under clear-sky conditions. For this clear-sky overpass, OMI BRD PBL data are much closer than PCA to the ground-based observation. Also OMI TRL product is larger than PCA and closer to the ground-based observations. Very large SO$_2$ total column values (up to more than 10 DU) are observed by the Brewer.
The largest satellite SO$_2$ total column (9.99 DU) is derived from the BRD algorithm from the standard product and it is very close to the Brewer values. OMI PBL product from direct broadcast gives a similar result (SO$_2$ total column is 9.50 DU).

28 September 2014. The Brewer observations show SO$_2$ total column values up to about 2 DU, thus, much smaller than the previous days. Two clear-sky overpasses for both OMI and OMPS are available. Both OMI PBL PCA data and OMPS PBL are missing for their first overpass of the day. For the second overpass, the PBL products are again very close to the ground-based observations, except for the OMI PBL product from the BRD algorithm which produces negative values. No OMI data from direct broadcast are available for this day.

29 September 2014. The largest SO$_2$ total column (13.9 DU) from Brewer measurements in September is recorded. SZA values up to 74–75° are reached during this last day of comparison. Most of the overpasses are available under cloudy conditions and the only clear-sky overpass corresponds to a very large OMPS pixel (number 1) and large SZA (75.1°). No OMI PBL products from PCA algorithm are available. Despite these limitations, the satellite observations are able to follow the daily evolution of SO$_2$ total column shown by the ground-based measurements. Both OMI and OMPS PBL products (the lightest shade of grey in Fig. 2 – lower right panel) show larger values around 09:00 UTC and decreasing during the day.

In order to get an idea about the precision of the satellite data at northern high latitudes, STDs for different products are derived from the box (10°E, 30°E) × (60°N, 70°N) for a presumably SO$_2$-free day (1 September 2014). For TRL, TRM and STL products, the obtained standard deviation values are very similar to those reported in the README file (see Sect. 2). For the PBL products, STDs of about 1.6 DU, 0.8 DU and 0.5 DU are obtained for OMI BRD, OMI PCA and OMPS BRD products, respectively. On 3 October 2014, with solar zenith angles about 70° or higher, the STD values are about 2.7 DU and 2.1 DU for OMI and OMPS PBL BRD products and about 1.1 DU for OMI PCA PBL data product. In addition, TRL STDs grow up to about 1.2 DU. This confirms that the quality of the satellite retrieval is lower for high solar zenith angles.
Assuming that the PBL products better represent the actual $SO_2$ profile distribution, the differences between satellite and ground-based observations are mostly within these uncertainties.

### 3.3 Effect of volcanic $SO_2$ emission on the surface-level concentration

Since the volcanic $SO_2$ plume was located at low altitudes, elevated concentrations of $SO_2$ were detected also at the surface. Figure 3 (right panel) shows the time evolution of the $SO_2$ concentrations observed during September 2014 at four air quality stations in northern Finland: Sammaltunturi, Kevo, Raja-Jooseppi and Oulanka. The locations of these sites are shown as triangles in Fig. 3 (left panel). Elevated $SO_2$ concentration values were measured starting on 5 September 2014, when also the $SO_2$ plume was observed over northern Finland for the first time after the volcanic eruption (Fig. 1 – top right panel). The highest hourly mean (about 180 $\mu g m^{-3}$) was found at Sammaltunturi during the night between 7 and 8 September 2014. The largest daytime peak at Sammaltunturi was observed on 10 September. During the same day concentration peaks were observed also at Raja-Jooseppi and Kevo stations. For comparison, the map of OMI PBL PCA product on 10 September is shown in Fig. 3 (left panel): the three northernmost stations (Sammaltunturi, Kevo and Raja-Jooseppi) were inside the $SO_2$ plume. This corresponds to the $SO_2$ concentration peaks observed in Fig. 3 (right panel) on 10 September. On the other hand, Oulanka was outside the plume during the same day and large $SO_2$ concentrations were only observed the morning after, 11 September 2014, because the plume was transported eastward (as seen, e.g., in the OMPS maps for the same day, available at sampo.fmi.fi). The $SO_2$ concentration peak in Kevo was smaller than in the other sites probably due to the lower altitude of the station.

Large $SO_2$ concentrations were measured during 13–19 September 2014 (up to about 50 $\mu g m^{-3}$ on 15 September), corresponding to $SO_2$ total column values up to about 1.5 DU measured from Brewer during the same period (not shown here). Because only sparse Brewer DS measurements are available during this period, these
data are not included in the comparison shown in Fig. 2. Elevated SO$_2$ concentrations (up to about 50 µg m$^{-3}$) were observed also on 27 and 29 September, when also the Brewer and the satellite measurements showed high SO$_2$ total column values. These concentrations were not as elevated as in the first half of September. This suggests that the SO$_2$ plume was located at higher altitudes during these two last days, thus only partially affecting the SO$_2$ concentration levels at the surface.

4 Summary and remarks

The validation results of satellite SO$_2$ retrievals derived from the OMI and OMPS instruments during the Icelandic Holuhraun fissure eruption in September 2014 are shown in this paper. The satellite observations were compared against ground-based Brewer measurements made in Sodankylä, Finland, which is located more than 2000 km from the emission source. On 29 September 2014, the Brewer measured the SO$_2$ total column record value (13.9 DU) for 2014. This is the second largest value measured in Sodankylä, after the Kasatatochi volcanic eruption in 2008 (17.2 DU).

The best agreement with the Brewer data was usually achieved with the satellite data products that assume a priori profile with SO$_2$ predominantly in the planetary boundary layer, i.e., the lowest levels of the atmosphere. This is reasonable since the SO$_2$ emissions in Iceland were emitted at tropospheric altitudes. In addition, exceptionally high SO$_2$ surface concentrations (up to about 180 µg m$^{-3}$) were observed in northern Finland, where the typical background SO$_2$ concentrations are close to zero. The air quality monitoring site located at the highest altitude, Sammaltunturi, was the most affected; hourly SO$_2$ concentration exceeded 100 µg m$^{-3}$ fifteen times. Record high concentrations were also detected at Oulanka, where the highest hourly, daily and monthly averages in the past ten years were recorded. The SO$_2$ concentration peaks in the timeseries correspond to enhanced SO$_2$ signals in the satellite data observed on the same days. This supports the hypothesis that the volcanic plume was located very close to the surface. These results show also that the satellite retrieval algorithms can
detect, qualitatively, the geographical location of the SO$_2$ plume, as compared to the ground-based stations.

The comparison between satellite and Brewer SO$_2$ total columns showed the best agreement during the first half of September. During this first period the BRD and the new PCA algorithms give very similar result for the OMI PBL product. Also the OMI DB products were available until 27 September. The direct-broadcast and standard products showed very similar results. The discrepancy between these products (both derived using the BRD algorithm) is at least partly related to the different residual correction methods: DB algorithm uses the “latitude band average” and the operational algorithm uses the “sliding median” residual correction method (see Yang et al., 2013, for details).

In the latter comparison period, the agreement with satellite products was weaker and the best agreement was found with PBL and TRL data products. The weaker agreement can be related to the less favourable satellite retrieval conditions, e.g., the large solar zenith angles (close or above 70°) and the frequent cloudy conditions. Less OMI PBL data from PCA algorithm were available, because the retrievals with slant column O$_3$ over 1500 DU (corresponding to high O$_3$ and large solar and viewing angles) are not included in the dataset. Also, the different OMI PBL products (PCA and BRD) gave less similar results than at the beginning of September. Despite these limitations, the satellite observations were still able to follow the daily evolution of the Brewer SO$_2$ total column values.

There are not many validation studies including satellite SO$_2$ data and even less at high latitudes. Because the solar and vertical zenith angles assumed in the satellite retrieval refer to lower-latitude regions, the satellite data are expected to underestimate SO$_2$ at high latitudes. This study highlights the need for improved retrievals at high latitudes and provides useful information about satellite SO$_2$ data quality during a volcanic eruption episode with several peculiarities: the SO$_2$ cloud was found close to the surface and strongly affected the air quality levels in northern Finland; the ground-based station Sodankylä is located at high latitudes (above 67° N), where the satellite
retrievals are particularly challenging because of high solar zenith angles and frequent cloudy scenes; the absolute SO$_2$ values are much higher than the background, reaching up to 9 DU in this study. Also, this is the first time when direct-broadcast SO$_2$ satellite data (from both OMI and OMPS instruments) are compared against ground-based observations.

At the time of writing of this paper, the Holuhraun fissure eruption is still ongoing and the eruption could continue during the northern hemispheric winter. Monitoring SO$_2$ during winter using UV-VIS instruments like OMI and OMPS becomes more difficult because of the reduced length of the day and increasing solar zenith angles. This can be already seen, e.g., in Fig. 1: the observable area is quickly reduced moving from the beginning to the end of September. For this reason, this validation study was limited to the month of September only. In addition to instruments like OMI and OMPS, SO$_2$ can be measured using satellite instruments like IASI (Infrared Atmospheric Sounding Interferometer, e.g., Clarisse et al., 2008) and AIRS (Atmospheric Infrared Sounder, e.g., Carn et al., 2005), which use the IR channels. However, they are less sensitive than the UV-VIS instruments to the tropospheric SO$_2$ signal.

Acknowledgements. The FMI work is supported by the Academy of Finland (INQUIRE project) and by TEKES (SPARK project).

The standard product data are distributed through the NASA’s MIRADAR website (http://mirador.gsfc.nasa.gov), while the direct-broadcast data are obtained from FMI’s SAMPO service (http://sampo.fmi.fi).

$^a$ Satellite SO$_2$ total column optimised for different altitude regions: planetary boundary layer (PBL), lower troposphere (TRL), mid-troposphere (TRM) and lower stratosphere (STL).

$^b$ Center of mass altitude (CMA).

$^c$ Band Residual Difference (BRD).

$^d$ Principal Component Analysis (PCA), available for OMI standard product only.

$^e$ Linear Fit (LF).
Table 2. Summary of the satellite overpasses at Sodankylä.

</table>

**Notes:**
- **a** Satellite data products. The options are: OMI SP (standard product); OMI DB (Direct Broadcast) and OMPS DB.
- **b** Cross track position (CTP). Ranging from 1 to 60 for OMI and from 1 to 36 for OMPS. The central pixels (nadir) are smaller than those at the edges of the swath.
- **c** Distance between the centre of the satellite pixel and Sodankylä.
- **d** Satellite-derived cloud fraction (CF).
- **e** Satellite-derived solar zenith angle (SZA).
- **f** Satellite SO$_2$ total column optimised for different altitude regions: planetary boundary layer (PBL), lower troposphere (TRL), mid-troposphere (TRM) and lower stratosphere (STL).
- **g** SO$_2$ total column from Brewer spectrophotometer direct sun (DS) measurements. The closest observations (within 30 min) to the satellite overpass time are taken into account.
- **h** OMI SP PBL product is processed using both Band Residual Difference and Principal Component Analysis algorithms (BRD / PCA).
Figure 1. \(\text{SO}_2\) total columns as seen from OMI SP TRL product during the Holuhraun fissure eruption for six days in September 2014. The dates (day/month) are indicated in the title of each panel. The blue crosses indicate the location of Sodankylä ground-based station.
Figure 2. SO$_2$ vertical columns in Sodankylä, Finland during selected days of September 2014. Black dots refer to ground-based Brewer measurements, circles to OMI SP and crosses to OMPS observations. Different colours correspond to different satellite products sensitive to different altitude regions: PBL (blue), TRL (green), TRM (red) and STL (light blue). The pink stars refer to the PBL product processed using the BRD algorithm. PBL, TRL, TRM and STL satellite products for cloudy scenes (cloud fraction larger than 0.3) are shown in grey (from light to dark grey, respectively) and should be considered with caution.
**Figure 3.** Left panel: OMI SP PBL (PCA algorithm) during 10 September 2014. The black cross indicates the location of Sodankylä. The triangles indicate the location of the air quality stations: Sammaltunturi (blue), Kevo (green), Raja-Jooseppi (red), Oulanka (light blue). Right panel: Timeseries of the SO$_2$ concentration in the northern Finland air quality stations in September 2014.
