Abstract

In recent years attention was increasingly paid to backscatter profiles of ceilometers as a new source of aerosol information. Several case studies have shown that – although originally intended for cloud detection only – ceilometers can provide the planetary boundary layer height and even quantitative information such as the aerosol backscatter coefficient $\beta_p$, provided that the signals have been calibrated. It is expected that the retrieval of aerosol parameters will become widespread as the number of ceilometers is steadily increasing, and continuous and unattended operation is provided. In this context however one should be aware of the fact that the majority of ceilometers emit wavelengths that are influenced by atmospheric water vapor. As a consequence, profiles of aerosol parameters can only be retrieved if water vapor absorption is taken into account. In this paper we describe the influence of water vapor absorption on ceilometer signals at wavelengths in the range around $\lambda = 910$ nm. Spectrally high resolved absorption coefficients are calculated from HITRAN on the basis of realistic emission spectra of ceilometers. These results are used as reference to develop a methodology (“WAPL”) for routine and near real time corrections of the water vapor influence. Comparison of WAPL with the reference demonstrates its very high accuracy. Extensive studies with simulations based on measurements reveal that the error when water vapor absorption is ignored in the $\beta_p$ retrieval can be in the order of 20% for mid-latitudes and more than 50% for the tropics. It is concluded that the emission spectrum of the laser source should be provided by the manufacturer to increase the accuracy of WAPL, and that 910 nm is better suited than 905 nm. With WAPL systematic errors can be avoided, that would exceed the inherent random errors of the Klett solutions by far.
1 Introduction

In the last few years a large number of autonomous single-wavelength backscatter lidars, so called ceilometers, has been installed. Several ceilometer networks are operated by national weather services on a 24/7 basis (e.g., Hirsikko et al., 2014). Meanwhile, the total number of such systems is almost 2000. Though originally designed for the detection of clouds only, in the last years more attention was paid to the potential of ceilometers for aerosol related retrievals: studies were devoted to the validation of transport models (e.g., Emeis et al., 2011; Wiegner et al., 2012) and to the assessment of the mixing layer height (e.g., Eresmaa et al., 2006; Münkel et al., 2007; Haefelin et al., 2011) taking advantage from the fact that aerosols are a good tracer for mixing processes in the troposphere. These studies often are based on the exploitation of the ceilometer signal rather than on quantitative physical parameters. Though there are differences in the mathematical details of the analysis, basically these algorithms use the gradient of the ceilometer signal in one way or another. Typically, the time resolution of “raw” data is in the order of 15–30 s and the spatial resolution is in the range of 10–15 m up to a height of 7.5 or 15 km depending on the ceilometer-type and its settings.

Being aware of the significance of aerosols for radiation, cloud physics and air quality recently the discussion came up if optical properties can be derived quantitatively from ceilometers. If so, ceilometer networks might help to fill observational gaps; this information could by of benefit in particular taking into account that aerosols are highly variable in time and space. As a consequence, recently first attempts were made to retrieve aerosol optical properties. Wiegner et al. (2014) show that the backscatter coefficient $\beta_p$ is the only parameter that can be determined with acceptable accuracy. Further quantities, such as the aerosol extinction coefficient $\alpha_p$ are prone to considerable errors if there are no additional information available, e.g. the magnitude of the lidar ratio $S_p$. Nevertheless, backscatter coefficients certainly are quite useful as they can be the basis for data assimilation and the validation of chemistry transport mod-
Ceilometers typically are working in the near IR, either at 1064 nm (e.g., Jenoptik, Lufft) or at 905–910 nm (e.g., Vaisala, Eliasson, Campbell). Both wavelengths are in a spectral range where aerosol scattering is clearly dominating scattering by air molecules (Rayleigh scattering). This facilitates the detection of aerosol layers but raises problems of the signal calibration that is required to derive $\beta_p$. The main difference between the two wavelengths is however water vapor absorption: between 900 and 930 nm a strong absorption band exists whereas there is no absorption at 1064 nm. This fact does not play a significant role when mixing layer heights are to be determined, however, water vapor absorption must be considered when profiles of $\beta_p$ shall be derived. This is e.g. true for most of the frequently used Vaisala ceilometers (CT25k, CL31, CL51).

To our knowledge, Markowicz et al. (2008) were the first who corrected signals of a Vaisala CT25k-ceilometer for water vapor before deriving aerosol optical properties. This was done for measurements in the framework of the United Arab Emirates Unified Aerosol Experiment (UAE$^2$) in 2004. Sundström et al. (2009) evaluating CL31 measurements from 2005 in Helsinki, restrict themselves to cases when they assumed that water vapor absorption can be neglected. The same assumption was made by Jin et al. (2015) using CL51 data. Madonna et al. (2014) mentioned the water vapor absorption when they compared ceilometers of Jenoptik (CHM15k), Vaisala (CT25k) and Campbell (CS135s) but did not consider it quantitatively. In comparisons of aerosol backscatter in the boundary layer derived from lidar and CL31 measurements (Mckendry et al., 2009; Tsaknakis et al., 2011) or from different ceilometers (Haeffelin et al., 2011) water vapor absorption was not considered, which is not critical as long as only mixing layer heights (e.g., Leroyer et al., 2013) or cloud base heights (e.g., Martucci et al., 2010) are determined. Emeis et al. (2007) avoided the problem by using a Vaisala
LD40 ceilometer working at 855 nm instead of the standard Vaisala systems. Wiegner et al. (2014) discussed the problem in a general way on the basis of simulated signals. They pointed out that the unknown emission spectrum of the diode laser and the unknown water vapor distribution can introduce significant errors, and that at least an approximative correction should be applied. However, a systematic and thorough study of the influence of water vapor absorption on aerosol retrievals was beyond the scope of that paper. In this paper we want to give further insight into this topic and provide a methodology that can routinely be applied to real measurements.

In the following section we give a short outline of different solutions of the lidar equation applicable in case of water vapor absorption. The sensitivity to atmospheric and instrumental parameters is investigated in a general way by means of high spectral resolution calculations of absorption on the basis of standard atmospheres. This constitutes the basis to develop a methodology (henceforward referred to as WAPL) for routine evaluation of ceilometer data; a detailed discussion is provided in Sect. 4. Section 5 includes a case study based on simulations and real measurements to demonstrate the basic features of WAPL, and a robust estimate of the order of magnitude of the systematic error of $\beta_p$ when absorption is neglected. A summary and future needs to improve aerosol retrievals based on ceilometer measurements conclude the paper.

2 Theoretical outline

2.1 Solution for the backscatter coefficient

For aerosol remote sensing by means of a backscatter lidar elastic scattering is considered, i.e., the emitted and received wavelengths $\lambda$ are the same, and the emitted spectrum is “narrow”. Thus, the lidar equation (Eq. 1) is normally treated as “monochromatic”, i.e., no wavelength-dependence of the optical properties is considered and the
wavelength is not explicitly included:

\[ P(z) = C_L \frac{\beta(z)}{z^2} T_p^2(z) T_m^2(z) T_{w,\text{eff}}^2(z) \]  

(1)

The lidar signal \( P \) is written as a function of height \( z \) assuming a vertically looking ceilometer. On the right hand side the transmissions of air molecules (subscript \( m \)) and particles (subscript \( p \))

\[ T_i = \exp \left\{ -\int_0^z \alpha_i(z') \, dz' \right\} \quad \text{with: } i \in \{m, p\} \]  

(2)

and the transmission of water vapor (subscript \( w \)) that is obligatory if wavelengths around 910 nm are considered. In view of the fact that the emission spectrum of a ceilometer can be much broader than the line widths within an absorption band, an effective water vapor transmission \( T_{w,\text{eff}} \) is included; details are given in Sect. 2.2. System characteristics are described by \( C_L \). The backscatter coefficient \( \beta \) can be separated into contributions from particles and air molecules

\[ \beta = \beta_p + \beta_m \]

The analytical solution of the lidar equation with respect to either \( \beta_p \) or \( \alpha_p \) is well established in the absence of trace gas absorption and commonly referred to as the “Klett solution” (e.g., Fernald et al., 1972; Klett, 1981). Under typical atmospheric conditions the \( \beta_p \) retrieval is preferable, in particular in cases of low aerosol concentration and/or long wavelengths, as under these conditions the retrieval is less sensitive to errors of the assumed lidar ratio.

The lidar equation with water vapor absorption (Eq. 1) can be solved in different ways for \( \beta_p \). All solutions can be expressed in this general form

\[ \beta_p(z) = \frac{Z_i(z)}{N_i(z)} - \beta_m(z) \quad \text{with } i = 1, 2, 3, 4 \]  

(3)
The first two approaches follow the solution described by Klett but with the additional water vapor absorption resulting in a more general form. If the range-integration is performed in forward direction from the overlap range \( z_{ovl} \) one gets

\[
Z_1(z) = z^2 P(z) T_{w,\text{eff}}^{-2}(z_{ovl}) \times \exp \left\{ -2 \int_{z_{ovl}}^{z} [(S_p - S_m)\beta_m - \alpha_{w,\text{eff}}] dz' \right\}
\]

(4)

and

\[
N_1(z) = C_L (1 - \varepsilon) - 2 \int_{z_{ovl}}^{z} S_p(z')Z_1(z')dz'
\]

(5)

Here, in contrast to the original Klett-solution, additionally the effective water vapor extinction coefficient \( \alpha_{w,\text{eff}} \) appears. Note, that using \( z_{ovl} \) as the lower boundary of the integrals in Eqs. (4) and (5) is an approximation applicable for cases of low overlap heights \( z_{ovl} \) and/or long wavelengths as pointed out by Wiegner and Geiß (2012). This approximation is very accurate in case of \( Z_1(z) \) at wavelengths not affected by water vapor absorption, otherwise the factor \( T_{w,\text{eff}}^{-2}(z_{ovl}) \) has to be considered. As we want to investigate the effect of water vapor absorption on \( \beta_p \) retrievals as precisely as possible (Sect. 5) we have also included the term \((1 - \varepsilon)\) for \( N_1(z) \) which is calculated as

\[
\varepsilon = 2 \int_{0}^{z_{ovl}} S_p(z')\beta(z')T_m^2(z')T_p^2(z')dz' \approx 2z_{ovl} S_p \beta(z_{ovl})
\]

(6)

and must be determined iteratively because \( \beta(z_{ovl}) \) is initially unknown. Using typical values one gets \( \varepsilon \approx 0.02 \) in accordance with Wiegner and Geiß (2012) where it was stated that \( \varepsilon \) is small compared to 1, but was set to 0 for the sake of simplicity.
If the range integration is done towards the lidar, slightly different equations are found: for $Z_2(z)$ we get

$$Z_2(z) = z^2 P(z) \exp \left\{ 2 \int_z^{z_{\text{ref}}} \left[ (S_p - S_m) \beta_m - \alpha_{w,\text{eff}} \right] dz' \right\}$$

(7)

and for $N_2(z)$

$$N_2(z) = \frac{z_{\text{ref}}^2 P(z_{\text{ref}})}{\beta_m(z_{\text{ref}}) + \beta_p(z_{\text{ref}})} + 2 \int_z^{z_{\text{ref}}} S_p(z') Z_2(z') dz'$$

(8)

with a “meteorological” reference value $\beta_p(z_{\text{ref}})$.

Two additional approaches are based on a simple re-arrangement of the lidar equation (Eq. 1):

$$P(z) T_{w,\text{eff}}^{-2}(z) = P'(z) = C_L \frac{\beta(z)}{z^2} \ T_p^2(z) T_m^2(z)$$

(9)

Then, the “standard” Klett solution, i.e., without an absorption term, can be applied to $P'$ (instead of $P$). As a consequence $Z_3(z)$ and $N_3(z)$ can be introduced as

$$Z_3(z) = z^2 P'(z) \exp \left\{ -2 \int_{z_{\text{ovl}}}^{z} (S_p - S_m) \beta_m \, dz' \right\}$$

(10)

and

$$N_3(z) = C_L (1 - \varepsilon) - 2 \int_{z_{\text{ovl}}}^{z} S_p(z') Z_3(z') \, dz'$$

(11)
They can be used instead of $Z_1(z)$ and $N_1(z)$ if the ceilometer has been calibrated absolutely. The solution corresponding to the backward integration ($Z_2(z), N_2(z)$) is

$$Z_4(z) = z^2 P'(z) \exp \left\{ 2 \int_z^{z_{\text{ref}}} (S_p - S_m) \beta_m dz' \right\}$$

(12)

and

$$N_4(z) = \frac{z_{\text{ref}}^2 P'(z_{\text{ref}})}{\beta_m(z_{\text{ref}}) + \beta_p(z_{\text{ref}})} + 2 \int_z^{z_{\text{ref}}} S_p(z') Z_4(z') dz'$$

(13)

For the second group again the knowledge of the profile of $\alpha_{w,\text{eff}}(z)$ is required but expressed in form of the transmission $T_{w,\text{eff}}(z)$, and applied to the raw signal before the actual inversion is done. This procedure was used by Markowicz et al. (2008).

Which of the four formulations is applied, mainly depends on the ceilometer signal and the meteorological conditions, e.g., a backward solution typically can only be applied to night time measurements and long temporal averages. The remaining choice between option 1 vs. option 3 or option 2 vs. option 4 is more or less a matter of personal preference.

The solution for $\beta_p$ finally can be found if the signals are calibrated. Thus either the boundary value at $z_{\text{ref}}$ (Rayleigh calibration), see Eqs. (8) and (13), respectively, or $C_L$ must be determined (absolute calibration), see Eqs. (5) and (11). Basically, the Rayleigh calibration can be understood as finding a range $z_{\text{ref}}$ where the slopes of the measured and an hypothetical signal of an aerosol-free atmosphere agree: in case of Eq. (8) the measured signal must be compared with a hypothetical signal of an aerosol-free, but possibly water vapor containing atmosphere, in case of Eq. (13) the water vapor corrected signal $P'(z)$ is compared with a hypothetical signal of an aerosol-free atmosphere. Under realistic meteorological condition it is very likely that in altitude ranges where no aerosols are present the water vapor concentration is also virtually
zero. Consequently, finding a reference height $z_{\text{ref}}$ from the signal slope should be straightforward, provided that the signal-to-noise ratio is sufficiently large in that altitude. However, in any case the water vapor absorption ($\alpha_{w,\text{eff}}$ or $T_{w,\text{eff}}$) must be estimated.

If the absolute calibration is applied, the lidar equation is solved for $C_L$, and $C_L$ can be determined if all other parameters are known (Wiegner and Geiß, 2012). This requirement is difficult to fulfill: as $\beta_p$ at $\lambda = 910$ nm cannot be determined independently by e.g. a reference lidar system, it must be extrapolated from $\beta_p$ at 1064 nm or interpolated between 532 and 1064 nm. The extinction coefficient $\alpha_p$ is estimated by means of an assumed lidar ratio. As a conclusion, not only the uncertainty of the estimated water vapor extinction influences the accuracy of $C_L$ but also the uncertainties of $\beta_p$ of the reference lidar, the wavelength dependence of $\beta_p$, and the lidar ratio. Thus, the measurements for the absolute calibration must be selected very carefully, in particular the presence of multi-layered aerosol distributions (possibly with different aerosol types) should be avoided to facilitate the wavelength extrapolation. In summary, absolute calibration of ceilometer measurements at $\lambda \approx 910$ nm is inherently more prone to errors than at 1064 nm.

### 2.2 Spectral dependence of optical properties

As already mentioned the lidar equation is expressed as a monochromatic formulation. If this approach should be used for ceilometers with an emitted spectrum of a few nanometers width within a water vapor absorption band, the wavelength dependence of the optical properties must be investigated. In particular, $\alpha_{w,\text{eff}}$ must be calculated.

For such small wavelength intervals the spectral dependence of $\alpha_m$ and $\alpha_p$ can be neglected as can easily be demonstrated (see Table 1): If we consider e.g. a spectral range of $\pm 2$ nm at a wavelength of $\lambda = 910$ nm, and assume $\alpha_p = 0.05 \text{ km}^{-1}$ and an Angström exponent $\kappa = 1.5$ as representative values for our measurement site at Munich, Germany, the particle extinction coefficient $\alpha_p$ (and $\tau_p$ correspondingly) varies...
by approximately ±0.3%. The variation of the squared transmission $T_p^2$ is one order of magnitude smaller. Even for larger optical depth the variation of $T_p^2$ is negligible. Note, that in Table 1 the thickness of the layer is assumed to be 1 km (according to the standard atmospheres Anderson et al., 1986). The corresponding variation of the Rayleigh extinction coefficient $\alpha_m$ (e.g., Bodhaine et al., 1999) is of the order of ±1%, however, as $\alpha_m$ is more than one order of magnitude smaller than $\alpha_p$ the squared transmission $T_m^2$ can also be considered as wavelength-independent (see Table 1).

The spectral variation of $\beta_p$ is similar to that of $\alpha_p$ as the lidar ratio $S_p$ can be expected to be almost constant in the spectral interval. The variation of $\beta_m$ is equal to the variation of $\alpha_m$ and thus somewhat larger, but as $\beta_m \ll \beta_p$ the total backscatter coefficient $\beta$ is also virtually wavelength-independent (approximately ±0.4%, see Table 1).

As a consequence only the wavelength-dependence of the water vapor absorption must be considered. If we understand the ceilometer measurement as a series of pulses at $N$ different wavelengths $\lambda_i$ (from an interval of a few nanometers width) and a weight $a_i$ as a measure of the frequency of occurrence of wavelength $\lambda_i$ or as a factor describing a wavelength dependence of the lidar constant we can express the lidar equation as follows:

$$P(z) = \frac{\sum_{i=1}^{N} a_i C_L \frac{\beta(z)}{z^2} T_p^2(z) T_m^2(z) T_w(z, \lambda_i)}{\sum_{i=1}^{N} a_i}$$

(14)

Here, $P(z)$ is “normalized to one shot” in accordance to Eq. (1). Then, the effective water vapor transmission $T_{w,\text{eff}}(z)$ can be defined as

$$T_{w,\text{eff}}^2(z) = \frac{\sum_{i=1}^{N} a_i T_w^2(z, \lambda_i)}{\sum_{i=1}^{N} a_i}$$

(15)

and the “spectral” lidar equation (Eq. 14) can be handled in the well known “monochromatic” way as already applied in Eqs. (1) and (9). The only remaining task is the determination of $T_{w,\text{eff}}^2$ or an equivalent quantity, e.g. the effective water vapor absorption...
coefficient $\alpha_{\text{w,eff}}$, as a function of height for the measurement time. If the relation between $\alpha_{\text{w,eff}}$ and $T_{\text{w,eff}}$ is defined as usual, see Eq. (2), we obtain for a layer from $z_1$ to $z_2$:

$$
\alpha_{\text{w,eff}} = \frac{1}{2(z_2 - z_1)} \ln \left( \frac{T_{\text{w,eff}}^2(z_1)}{T_{\text{w,eff}}^2(z_2)} \right)
$$

(16)

Now, $\alpha_{\text{w,eff}}$ can be used in Eqs. (4) and (7). The knowledge of $\alpha_{\text{w,eff}}$ or $T_{\text{w,eff}}$ is also a prerequisite for the calibration of the signals as discussed in Sect. 2.1.

3 Effective water vapor absorption

For the determination of the effective absorption coefficients of water vapor $\alpha_{\text{w,eff}}$ we use the atmospheric radiative transfer simulator (ARTS, Buehler et al., 2005) in the wavelength interval from 895 to 930 nm, (wavenumbers $\tilde{\nu}$ between 11 173 and 10 753 cm$^{-1}$), though for ceilometer applications the range between 900 and 925 nm probably would be sufficient. The spectral resolution $\Delta\tilde{\nu}$ was set to 0.01 cm$^{-1}$, resulting in 42 050 different calculations. Spectroscopic data are based on the HITRAN (Rothman et al., 2005) data base and the MT-CKD continuum model (Clough et al., 2005), the same data set as used by Gasteiger et al. (2014). Spectral absorption cross sections depend on temperature, pressure and the water vapor concentration, consequently, these profiles are required as input. Note, that the output of the ARTS-simulations are spectral optical depths of water vapor. Profiles of the water vapor number concentration $n_w$ (in m$^{-3}$) are determined according to

$$
n_w = 7.25 \times 10^{22} \rho_w R_w
$$

(17)
with $R_w = 0.462 \text{ J g}^{-1} \text{ K}^{-1}$ as the gas constant of water vapor, the absolute humidity $q_w$ (in g m$^{-3}$)

$$q_w = \frac{f_{\text{rel}} p_s}{R_w T}$$  \hspace{1cm} (18)

and the water vapor saturation pressure $p_s$ that can be derived from Magnus’ formula.

The constant in Eq. (17) results from the standard values for temperature, pressure and number concentration of air molecules, and is given in K(Nm)$^{-1}$.

The maximum height of the model atmosphere was set to 10 km which is certainly sufficient in view of the measurement range of ceilometers.

To investigate the influence of different water vapor distributions we use 6 standard atmospheric models (US-standard, mid-latitude summer and winter, subarctic summer and winter, tropical; Anderson et al., 1986) for our simulations. The water vapor content expressed as precipitable water $w$ of these atmospheres is between $w = 4.2 \text{ kg m}^{-2}$ (subarctic winter) and $w = 41.7 \text{ kg m}^{-2}$ (tropical). The vertical resolution of all profiles is 1 km below 25 km. As the actual central wavelength and the width of the emission spectrum of a ceilometer could be temperature dependent and not always known in detail we also investigate different spectra. For the CL51 ceilometer e.g., $\lambda_0 = 910 \pm 10 \text{ nm}$ at 25°C with a drift of 0.27 nm K$^{-1}$ is specified by Vaisala. We assume a Gaussian shape of the spectrum with $\lambda_0$ between 901 and 919 nm, and a full width at half maximum (FWHM, henceforward referred to as $\Delta \lambda$) between 1.0 and 4.0 nm. According to Vaisala, $\Delta \lambda$ is of the order of 3.4 nm. From these parameters the weights $a_i$ required for Eq. (15) are calculated. Note, that the relation between the standard deviation of the Gauss function $\sigma$ and $\Delta \lambda$ is

$$\text{FWHM} = \Delta \lambda = 2\sigma \sqrt{2\ln 2} \approx 2.355 \sigma$$  \hspace{1cm} (19)

Figure 1 gives an example of the spectral transmission for the mid-latitude summer atmosphere and the modeled emission spectra of the laser. Shown is $T_w^2(\lambda)$ from the
surface to 1 and 10 km, respectively, and the Gaussian curves for $\lambda_0 = 910$ nm, and $\Delta \lambda = 2.0$ nm and $\Delta \lambda = 4.0$ nm as a “narrow” and a “broad” case. It is obvious that in all cases the width of the emission spectrum is much larger than the spectroscopic structure of the absorption so that in any case a large number of strong and weak lines are averaged. Nevertheless it is expected that the effective transmission depends on $\lambda_0$ and $\Delta \lambda$ as Fig. 2 may illustrate.

It shows $\alpha_{w, \text{eff}}$ in the lowermost layer of the model atmosphere as a function of $\lambda_0$ and its sensitivity on $\Delta \lambda$. The 6 standard atmospheres can be distinguished by color whereas the different $\Delta \lambda$ can be identified by the symbols. It is obvious that different water vapor contents of the standard atmospheres have the most significant influence on $\alpha_{w, \text{eff}}$ with largest values for the tropical case. This points out that it is crucial to have water vapor profiles as available from radiosondes (for their accuracy see, e.g., Miloshevich et al., 2009; Dirksen et al., 2014) or analyses of NWP models (e.g. NFS by NCEP or IFS by ECMWF) for the correction of ceilometer measurements. It can also be seen that for a given atmosphere $\alpha_{w, \text{eff}}$ changes with $\lambda_0$ quite differently: e.g., absorption increases by almost a factor of 2 from $\lambda_0 = 905$ to 908 nm, whereas it varies only within less than 10 % between $\lambda_0 = 908$ to 918 nm as indicated by the dashed lines. Thus, the error of the absorption coefficient $\alpha_{w, \text{eff}}$ due to a temperature induced change of $\lambda_0$ by 1 or 2 nm can be quite different. The variability with $\Delta \lambda$ depends on $\lambda_0$ but is in most cases comparably small.

For the analysis of actual ceilometer data a better vertical resolution than that of the standard atmospheres is desired resulting in a significant increase of computing time and mass storage. For compensation a reduction of the spectral resolution of ARTS could be an option. As a consequence, we have repeated all calculations with different spectral resolutions using $\Delta \tilde{\nu} = 0.01 \, \text{cm}^{-1}$ as reference. It was found that for a reduced spectral resolution of $\Delta \tilde{\nu} = 0.1 \, \text{cm}^{-1}$ the relative deviation of $\alpha_{w, \text{eff}}$ from the reference is less than $2 \times 10^{-3}$ for $\Delta \lambda \leq 2$ nm and less than $5 \times 10^{-4}$ for $\Delta \lambda \geq 2.5$ nm. In case of $\Delta \tilde{\nu} = 0.2 \, \text{cm}^{-1}$ the relative deviation is still small, but not negligible: in most cases it is
between $1 \times 10^{-2}$ and $1 \times 10^{-3}$. Thus, it is justified to reduce the spectral resolution of ARTS to $\Delta \tilde{\nu} = 0.1$ cm$^{-1}$.

We conclude that for correcting ceilometer data influenced by water vapor absorption the following information – ordered by decreasing relevance – is essential: the water vapor concentration profile, the central wavelength of the diode laser and the width of its spectrum.

4 Correction function for water vapor absorption

As already stated in Sect. 2, profiles of $T^2_{w, \text{eff}}(z)$ are required to correct ceilometer measurements for water vapor absorption. Calculations with high spectral resolution taking into account the actual water vapor, temperature and pressure distribution, are however too expensive for large data sets or near real time applications. For this purpose we aim at an approximative solution. As reference we define ARTS simulations with a spectral resolution of $\Delta \tilde{\nu} = 0.1$ cm$^{-1}$, i.e. 4206 simulations for the spectral range between 895 and 930 nm.

4.1 Mid-latitude case

As input for our water vapor absorption calculations we choose data from all radiosonde ascents of the year 2012 at Oberschleißheim (8 km northwest of the ceilometer site in Munich, WMO station identifier 10 868), that reached at least 10 km above the ground. This results in a total number of 647 profiles of $T$, $p$ and relative humidity $f_{\text{rel}}$. These soundings are regarded as representative for continental mid-latitude sites, the annual mean and the standard deviation of the atmospheric water vapor content is $w = 15.9 \pm 7.7$ kg m$^{-2}$. With the spectral optical depths of water vapor $\tau_w$ provided by the ARTS-calculations the corresponding absorption cross section $\sigma_w(t_i, \lambda_j, z_k)$ at each wavelength grid point $j$, ($j \leq 4206$), and each radiosonde ascent (consecutively numbered according to time $t_i$, here $i \leq 647$) at level $k$ ($k \leq 1000$, for 10 m vertical resolu-
tion) can be derived from Eq. (20)

\[
\sigma_w(t_i, \lambda_j, z_k) = \frac{\tau_w(t_i, \lambda_j, z_k)}{\Delta z n_w(t_i, z_k)}
\] (20)

In the spectral range between 895 and 930 nm the absorption cross section covers a wide range between \(\sigma_w = 10^{-26} \text{ cm}^2\) and \(\sigma_w = 10^{-21} \text{ cm}^2\), and the height-dependence is quite variable. It can increase or decrease with height depending on the distance of the specific wavelength from a line center.

Two extreme cases are shown in Fig. 3: at \(\lambda = 908.957 \text{ nm}\) (left panel) the variability of \(\sigma_w\) over the 647 atmospheric situations is very small, i.e. the 10 %-percentile and the 90 %-percentile deviate in the order of \(\pm 0.5\%\) from the average \(\overline{\sigma_w}(\lambda_j, z_k)\) at each level. At \(\lambda = 905.885 \text{ nm}\) (right panel) one of the rare cases occur where the deviation is in the order of \(\pm 10\%\). If we consider all levels \(k\) and all wavelengths \(j\) (i.e. a total of 4.2 million cases), the deviation of \(\sigma_w\) from the corresponding average is below 5 % in 81 % of all cases, and below 10 % in 97 % of all cases. If the spectral range is restricted to wavelengths smaller than 925 nm, the corresponding values are even larger with 87 and 99 %, respectively. The “spikes” are numerical effects caused by the very high vertical resolution of the ARTS calculations and occur in cases of very strong gradients of the relative humidity measured by the radiosondes. However, these cases are quite rare as can be deduced from the smooth curves of the percentiles.

Thus, it can be expected that it is sufficient for the water vapor correction to consider at each wavelength one profile of \(\overline{\sigma_w}\) averaged over “all” atmospheric states. As a consequence we store the averaged absorption cross section \(\overline{\sigma_w}(\lambda_j, z_k)\) with a spectral resolution of \(\Delta \tilde{\nu} = 0.1 \text{ cm}^{-1}\) and a vertical resolution of 10 m in an archive (netcdf format).

On the basis of these findings a water vapor correction scheme for routine evaluation of ceilometer data, named “WAPL”, has been developed: from radiosonde profiles or numerical models the water vapor number density \(n_w\) is calculated according to Eqs. (17) and (18). The emission spectrum \((\lambda_0, \Delta \lambda)\) of the laser must be estimated.
for the individual ceilometer and might be time-dependent. With the tabulated mean absorption cross-section $\sigma_w(\lambda, z)$ of the above mentioned archive an (approximative) water vapor transmission $T_{w, prx}(\lambda, z)$ can be calculated. Finally, the effective (approximative) water vapor transmission $T_{w, eff, prx}(z)$ is derived analogously to Eq. (15) and used to determine $\beta_p$ (Eq. 3). To characterize the accuracy of this procedure we define a function $G$ as

$$G(t_i, z) = \frac{T^2_{w, eff, prx}(t_i, z)}{T^2_{w, eff, ref}(t_i, z)} - 1$$  (21)

To get independent results the accuracy of WAPL is tested using all radiosonde ascents of the year 2013 (636 cases) of Oberschleißheim. The water vapor content of $w = 14.7 \pm 7.1 \text{ kg m}^{-2}$ is similar to the previous year. From these data the actual water vapor number concentration can readily be calculated. By assuming a Gaussian-shaped emission spectrum of the laser diode with a realistic value of $\Delta\lambda = 3.5 \text{ nm}$, considering the spectral range of $\pm 3$ standard deviations (i.e., $2.548 \Delta\lambda$, see Eq. 19), and using our reference spectral resolution of $\Delta \tilde{\nu} = 0.1 \text{ cm}^{-1}$, this requires 1080 out of 4206 “individual” wavelengths ($N$ in Eq. 15) to calculate $T^2_{w, eff, prx}$. Finally we get 636 profiles of $G(t_i, z)$.

An example of the performance of WAPL, expressed in terms of $G$, is given in Fig. 4 for $\lambda_0 = 905 \text{ nm}$ and $\Delta\lambda = 3.5 \text{ nm}$. It can be seen that the averaged $G(z)$ and the median $G_{50}(z)$ are virtually zero (left panel), the percentiles ($G_{10}(z)$ and $G_{90}(z)$) are within $\pm 0.3\%$, and that even the minimum and maximum values caused by the rare spikes mentioned above stay within $-0.5$ and $0.3\%$ for all radio soundings and all heights. Similar results can be found for other $\lambda_0$: as can be anticipated from Fig. 2 the errors are slightly larger around 907 nm and smallest around 912 nm, but the absolute values of $G_{10}(z)$ and $G_{90}(z)$ are never larger than 0.3%. So we conclude that the annual variability of $p$ and $T$ has no significant influence on $\sigma_w$ and consequently WAPL is suitable to correct the $\beta_p$ retrieval for water vapor.
This conclusion remains valid if we reduce the vertical resolution of the stored $\bar{\sigma}_w$ to 100 m, but not if we reduce the spectral resolution (we have considered $\Delta \tilde{\nu} \leq 1$ cm$^{-1}$). Only if we select $\Delta \tilde{\nu} = 0.2$ cm$^{-1}$, the percentiles $G_{10}(z)$ and $G_{90}(z)$ are within $-0.4$ and 0.3%. But as soon as $\Delta \tilde{\nu} \geq 0.3$ cm$^{-1}$ (Fig. 4, center and right panels for $\Delta \tilde{\nu} = 0.3$ cm$^{-1}$ and $\Delta \tilde{\nu} = 0.5$ cm$^{-1}$, respectively) the deviations generally increase and $T_{\text{eff, ref}}^2(t_i, z)$ is systematically over- or underestimated. As can be seen e.g. in the rightmost panel of Fig. 4, the transmission is systematically overestimated; $G_{50}(z)$ is in the order of 0.5%. Note, that the accuracy of the approximation is not correlated with $\lambda_0$ and the spectral resolution. At $\lambda_0 = 906$ nm the median $G_{50}(z)$ is e.g. virtually zero for $\Delta \tilde{\nu} = 0.8$ cm$^{-1}$, but up to $+1.3\%$ for $\Delta \tilde{\nu} = 0.7$ cm$^{-1}$, and $-2.3\%$ for $\Delta \tilde{\nu} = 0.9$ cm$^{-1}$. Due to their “unpredictable” magnitude these errors can hardly be implemented in an error analysis of the ceilometer retrieval. Thus, we recommend to use a spectral resolution of $\Delta \tilde{\nu} \leq 0.2$ cm$^{-1}$.

### 4.2 Tropical case

To investigate the validity of WAPL and to test whether one archived set of annual averages of water vapor absorption cross sections $\bar{\sigma}_w$ is sufficient for global applications we have repeated the calculations for Acapulco, Mexico (16.84° N, 99.93° W, station identifier 76805). The water vapor distribution significantly differs from the situation at Oberschleißheim: the annual mean of the water vapor content $w = 46.0 \pm 11.4$ kg m$^{-2}$ is almost three times larger and the variability is larger as well. We use radiosonde ascents of 2012 (453 cases) as reference and data from 2013/14 (512 cases) for the validation.

To illustrate the results in comparison to the mid-latitude station at Oberschleißheim Fig. 5 shows the profile of water vapor absorption cross section $\bar{\sigma}_w(\lambda, z)$ at the same two wavelengths as before (see Fig. 3). It is obvious that the height-dependence is similar, however, the absolute values of $\bar{\sigma}_w(\lambda, z)$ are slightly larger at Acapulco for most height levels. The variability of the sample of one year’s ascents is somewhat smaller:
at both wavelengths, especially at $\lambda = 905.885$ nm, the percentiles are closer to the average for the Acapulco site. The “spikes” of the absorption cross section profiles are more frequent than for the mid-latitude case, likely a result of larger errors of the humidity measurements of the radiosondes. However, these cases do not prevent the determination of smooth $\sigma_w$ profiles.

The accuracy of WAPL is again expressed in terms of $G(t, z)$, see Eq. (21). The results are very similar to the previous mid-latitude case and the same conclusions hold. If a spectral resolution of $\Delta \tilde{\nu} = 0.1 \text{ cm}^{-1}$ is used, $G_{50}(z)$ is virtually zero for all $\lambda_0$ and all levels, and the percentiles are within $\pm 0.2 \%$. Largest deviations occur for poor spectral resolution and are up to $\pm 4.0 \%$.

4.3 Sensitivity to climate zone

It has been shown that annual mean absorption cross sections of water vapor can be used for routine applications. We want to briefly discuss whether it is necessary to provide $\sigma_w(\lambda, z)$ tables for the site of the ceilometer, or if tables derived for other sites are acceptable. For this purpose we apply WAPL as introduced above, but use the mean absorption cross sections found for the mid-latitudes for the tropical site and vice versa. In contrast to the previous examples, $\lambda_0 = 912$ nm is selected for Fig. 6, as for this wavelength the effect is largest.

It can be seen (left panel) that using the mid-latitude absorption cross sections for the tropics results in a overestimate of the effective transmission. As a result of the previous discussion only the spectral resolution of $\Delta \tilde{\nu} = 0.1 \text{ cm}^{-1}$ is shown. The median $G_{50}(z)$ is up to 1.5 %, for shorter wavelengths (e.g. $\lambda_0 = 905$ nm, not shown) the overestimate is smaller and $G_{50}(z)$ is below 0.35 %. Inspection of the spectral absorption cross sections shows that for most of the wavelength grid points $\sigma_w$ is slightly larger under tropical conditions. Thus, absorption is underestimated when the values for the mid-latitudes are used, and consequently the transmission is overestimated. For reduced spectral resolutions $G_{50}(z)$ of up to $+4.5 \%$ can be found. In very few cases an underestimate of
the transmission can occur, up to \(-3.5\%\). This confirms our previous conclusion that a reduced spectral resolution shall not be considered.

For the sake of completeness we have also investigated the inverse effect, i.e., the \(\bar{\sigma}_w(\lambda, z)\) table derived for the tropical site is used for the mid-latitude site Munich. In this case a smaller systematic error of \(G_{50}(z)\) is found: for \(\lambda_0 = 912\,\text{nm}\) it is below 0.5\% (see Fig. 6, right panel), for shorter wavelength even smaller.

We conclude that \(\bar{\sigma}_w\) derived from a climatology of the same station should be used for the water vapor correction. If this is however not available mean values from other stations can be applied as a systematic error, even in the extreme case discussed above, is below 1–2\% and thus seems to be acceptable.

5 Examples of water vapor correction

The main objective of this section is to show the magnitude of the error of the particle backscatter coefficient \(\beta_p\) when the absorption of water vapor is not taken into account. Having water vapor absorption cross sections from WAPL and \(n_w\) from radiosonde ascents, \(T_{w,\text{eff}}^2\) and “water vapor corrected” signals \(P'(z)\), see Eq. (9) can be calculated straight-forwardly and a correction of ceilometer signals for water vapor absorption is possible.

To get realistic conclusions, it is reasonable to use measurements of a CL51 ceilometer. Measurements were available for a limited period of a few months in 2012 and took place at the roof platform of the Meteorological Institute of the Ludwig-Maximilians-Universität at Munich (48.148° N und 11.573° E, 539 m above mean sea level). Inspection of the CL51-data revealed that the signals exhibit a significant distortion in the free troposphere. As a consequence it was necessary to consider a “combination” of measurements and simulations in the following. Co-located and coincident measurements with a CHM15kx could be used for plausibility checks; a strict validation is in principle not possible as explained in Sect. 2.1.
5.1 Case study

For illustration, measurements of 17 March 2012 are shown in Fig. 7. In the left panel the range corrected signal $P(z)z^2$ of the CL51 (black) averaged over 2 h (02:00–04:00 UTC) in arbitrary units is plotted. The mixing layer below 1 km and an elevated layer (between 1.3 and 2.2 km) are clearly visible. For higher altitudes however the CL51 signal is quite noisy and does not show the expected slope of a “Rayleigh signal”. The corresponding signal of the CHM15kx (green) is shown for comparison. Its shape much closer follows the Rayleigh-signal (red dashed line), thus it can be assumed to be more realistic. Note, that the signals are scaled to match at 0.5 km. In the right panel the profiles of the relative humidity $f_{\text{rel}}$ (in %) and water vapor number concentration (in $10^{23}$ m$^{-3}$) are shown to illustrate the vertical water vapor distribution ($w = 6.0 \text{ kg m}^{-2}$). They are derived from the radiosonde of Oberschleißheim at 00:00 UTC.

From Fig. 7 it is clear that it is impossible to apply a Rayleigh-calibration to this CL51-signal and to retrieve $\beta_p$ by the backward algorithm (e.g., from $Z_4(z)$ and $N_4(z)$). In case that an absolute calibration is possible, i.e., $C_L$ is known, it will however be possible to derive $\beta_p$ by calculating $Z_3(z)$ and $N_3(z)$, but only for the altitude range not affected by the distortion, assumedly up to 2.2 km.

As it is beyond the scope of this paper to discuss the quality of ceilometer data – according to our experience from other studies the signal-quality may change even between instruments of the same model – and how measurement errors possibly might be corrected, we decided to model realistic ceilometer signals (influenced by water vapor) based on the CHM15kx-measurements. The advantage of this approach is threefold: first we can consider profiles of aerosol properties that are realistic for the site, second the forward and the backward solution can be tested, and third the water vapor effect is not obscured by measurement artefacts. Thus, our conclusions can be applied more generally.

For the assessment of the influence of the water vapor absorption we at first retrieve $\beta_p$ at 1064 nm from the Jenoptik ceilometer and converted it to several wavelengths
λ₀ around 910 nm by assuming an Angström exponent κ = 1.5 and a wavelength-independent lidar ratio of S_p = 55 sr. The corresponding aerosol optical depth at 532 nm is τ_p = 0.23, which is somewhat above the annual average for Munich. All other relevant optical properties are derived from the radiosonde ascent. We assume that the lidar constant C_L is known and that the emission spectrum of the ceilometer can be described by λ₀ and Δλ = 3.5 nm. Finally, the Eqs. (10) and (11) as discussed in Sect. 2.1 are used for the β_p retrieval at λ₀. Note, that an overlap correction as determined from horizontal measurements in March 2013 (Wiegner et al., 2014) is not required for measurements performed in 2012.

Two representative results of the retrieved β_p profile at two wavelengths λ₀, 907 nm (Fig. 8, left panel) and 912 nm (right panel) assuming the water vapor distribution of 17 March 2012 are shown. Here, we have not considered the typical retrieval errors of the analytical solution (e.g., due to wrong estimates of S_p and errors of C_L, see e.g. the discussion in Wiegner et al., 2014 for the CHM15kx-ceilometer) as we want to elaborate the water vapor effect. The retrieved β_p is determined with consideration of the water vapor absorption, i.e., P’(z) is used in Z₃(z) and N₃(z) and the correct λ₀. If we take into account, that under realistic conditions the assumption of λ₀ might be wrong by ±1 or 2 nm, the resulting profiles (green curves) are moderately shifted (left panel) or virtually unchanged (right panel). This is a consequence of the different spectral dependence of water vapor absorption (compare Fig. 2) that is much stronger at 907 nm. Thus, wrong assumptions of λ₀ have a larger influence at this wavelength. If the signal is treated as not being affected by water vapor, henceforward referred to as β_p*, the aerosol backscatter coefficient is significantly lower (red curves): this effect is more pronounced at 912 nm as water vapor absorption is stronger at this wavelength, see again Fig. 2.

Additional insight in the effect of water vapor absorption on the retrieval is given in Fig. 9 where the ratio β_p*/β_p for 4 wavelengths (905, 908, 911, and 914 nm, solid lines) is shown. It can be seen that the underestimate of the aerosol backscatter coefficient is increasing with height and amounts between 5 and 10 % for the boundary layer, and
between 10 and 20% for the elevated layer. In the free troposphere above 2.2 km the effect is even larger but less relevant as long as the low signal-to-noise ratio or signal distortion prohibits any aerosol retrieval. The horizontal lines indicate the uncertainties of the $\beta_p^*/\beta_p$ ratios if the above mentioned uncertainty of $\lambda_0$ of ±2 nm is taken into account. The underestimate is largest at 911 and 914 nm, whereas at 908 and 905 nm the uncertainty is much larger. In other words, the correction of ceilometer signals is either small with a large uncertainty or large with a small uncertainty. Our simulations show that ignoring water vapor may lead to negative $\beta_p^*$ in the free troposphere. If not over-compensated by signal distortions as shown in Fig. 7, such unrealistic values can be used as a warning to treat the retrieved profile with caution.

If the same investigations are carried out for different aerosol loads – for this purpose we have multiplied the particle backscatter coefficient by a factor of 0.5 and 2.0, respectively – our results in general are confirmed. Under clear conditions ($\tau_p = 0.12$ at 532 nm) the error of ignoring water vapor is somewhat larger, under turbid conditions ($\tau_p = 0.44$) it is smaller. As an example the corresponding $\beta_p^*/\beta_p$ ratios have been added for 905 nm (Fig. 9): the short dashed line refers to the turbid case, the long dashed line to the clear case and reaches underestimates of approximately 15% in the elevated layer (approximately 22% at 914 nm, not shown).

By using a “simulated measurement” we can also apply the backward integration with $Z_4$ and $N_4$ (Eqs. 12 and 13); under realistic conditions this will be restricted to temporal averages over typically two hours during night time, to cloud-free conditions and high quality ceilometer data. We know from the simulation set-up (17 March 2012) that at an altitude of 8 km the aerosol backscatter coefficient is zero and water vapor absorption is negligible; thus the Rayleigh calibration can be applied. The resulting $\beta_p$ profiles are shown in Fig. 10: again $\lambda_0 = 907$ nm (left panel) and 912 nm (right panel) are selected. It is obvious that ignoring the water vapor contribution leads to a $\beta_p^*(z)$ that overestimates the true aerosol backscatter coefficient. Compared to Fig. 8 the accuracy of the retrieval for the elevated layer and the mixing layer are however different. The overestimate is only 5% in the elevated layer and around 10–15% in the mixing layer.
The reason is that the absorption between the reference height and the lower boundary of the elevated layer is small due to the low water vapor concentration (see Fig. 7, right panel) and only becomes significant in the mixing layer. This strong absorption does however not influence the retrieval of the upper layers due to the downward direction of the integration.

Corresponding to the above discussion we also show ratios of the two retrievals $\beta_p^*/\beta_p$ in case of the backward integration in Fig. 11. The same 4 wavelengths are selected. It is obvious that the neglect of water vapor will result in an overestimate. It can be seen that again at the retrieval is better for the shorter wavelengths (905 and 908 nm) but with a quite high uncertainty if the emitted wavelength is not known precisely. For the longer wavelengths the deviation from the correct retrieval is larger but not much affected by the $\lambda_0$ uncertainty. In most altitudes the systematic error of $\beta_p(z)$ is smaller if the backward integration is applied, only in the lowermost atmosphere the retrieval is worse. This might be an issue because these levels are of particular interest for air quality studies.

Analogously to the previous discussion we have included in Fig. 11 the $\beta_p^*/\beta_p$ ratios of the “clear” and the “turbid” case for one wavelength (905 nm). Similar to Fig. 9 it can be seen that the water vapor effect is somewhat larger under clear conditions (long dashed line in Fig. 11) and can exceed 10% in the lowermost troposphere.

5.2 Estimate of a climatological average

The case study discussed in the previous section – based on 17 March 2012 – was carried out for a relatively low water vapor content. However, as the water vapor distribution shows a large spatial and temporal variability, it is not justified to understand the results from a single case as a generally applicable number for the magnitude of the $\beta_p$ error when water vapor is ignored. In spite of the large variability, we try to give an order of magnitude of this error by considering the annual variability of the water vapor content at Munich and Acapulco. For this purpose we use the constant aerosol distribution as before but change $n_w(z)$ according to the radiosonde ascents over one
year. Figure 12 shows the annual mean of $\beta_p^*/\beta_p$ for 2013 for Oberschleißheim (solid lines) and Acapulco (dashed lines), note, that the scale is different to Fig. 9. It can be seen from the standard deviation (horizontal lines) that the annual variability is quite high. As a consequence only orders of magnitude of the error are given below to stress the necessity of a correction for water vapor absorption in each individual case. Application of the forward algorithm results in an underestimate between 5 and 25% for the mid-latitude site and at least 10% and up to a factor of 2 for the tropical site. The corresponding results for the same year applying the backward algorithm are shown in Fig. 13. As expected from the above case study the errors are smaller for the elevated layer and slightly larger in the mixing layer. The mean overestimate of $\beta_p$ in the mixing layer is in the order of 20% (mid-latitudes) and 35% (tropics).

6 Summary and conclusions

If ceilometers, emitting radiation in the spectral range around 905–910 nm, shall be used to derive aerosol optical properties in a quantitative way, the signal must be corrected for water vapor. In this paper a methodology named WAPL is introduced that does not require time consuming absorption calculations with high spectral resolution but relies on tabulated water vapor absorption cross sections. It has been shown that the inherent error of this approximation is in the order of only 0.3% and thus virtually negligible. Furthermore, it has been demonstrated that these tabulated values need not necessarily be determined for the site of the ceilometer; this allows to use one data base for a network of ceilometers. The corresponding error is expected to be below 1%.

To apply WAPL, the emitted spectrum of the laser diode should be known or at least a reasonable estimate must be available. It has been shown that the water vapor correction is more accurate at wavelengths around 910 nm than around 905 nm. The uncertainties of the water vapor correction are, however, significantly smaller than the error if water vapor is totally ignored as has usually been done in the past. To benefit from
WAPL as much as possible the laser spectrum should be provided by the manufacturer; if the laser source is not temperature-stabilized the emitted wavelengths should be specified as a function of temperature. In this paper we have assumed a Gaussian curve with a FWHM $\Delta \lambda$ of 3–4 nm.

Due to the large temporal and spatial variability of the water vapor distribution it is not possible to give a unique number of the error when water vapor absorption is not taken into account. To get an indication of its magnitude we have studied a number of simulations based on a realistic aerosol distribution at Munich and water vapor distributions over one year at Munich and a tropical site. It was found that the systematic error of the aerosol backscatter coefficient $\beta_p$ is in the order of 10% for mid-latitude meteorological conditions but can reach 50% and more in the tropics, and thus can exceed the errors of the Klett retrieval by far. The magnitude of the error furthermore depends on the inversion scheme (forward or backward integration). It should be kept in mind that other error sources significantly contribute to the overall error of $\beta_p$, in particular the accuracy of the ceilometer signal itself, that might prevent a quantitative evaluation of the measurement. We want to emphasize that a strict validation of WAPL is not possible at the moment due to a number of assumptions that are required to extrapolate from a wavelength not influenced by water vapor absorption to 905–910 nm. For this purpose dedicated validation campaigns with the participation of different ceilometer models are planned, using advanced lidar systems and photometers to characterize the vertical aerosol distribution. In this context, a careful selection of adequate meteorological situations is indispensable, i.e., conditions with changing aerosol properties with height should be avoided. But for physical reasons it is certainly useful to apply the water vapor correction even if the strict validation is still missing; it will help to avoid a significant systematic error of the retrieved $\beta_p$.

Finally we again want to emphasize that ceilometers were primarily designed for the determination of cloud heights, and that attempts to retrieve aerosol properties only came up very recently. We expect that in near future the number of unattended and automated ceilometers and backscatter lidars will further grow, and that the hardware
and proprietary software might be adapted “towards aerosols”. As a consequence it can be anticipated that a significant data set of signals at wavelengths around 910 nm will be available for aerosol remote sensing. Then, water vapor correction must be an indispensable part of any data evaluation scheme.

Acknowledgements. We gratefully acknowledge Klaus Schäfer and Carsten Jahn (Karlsruher Institut für Technologie (KIT) – IMK-IFU) for the provision of the CL51 ceilometer during several months in 2012. The radiosonde data were downloaded from http://weather.uwyo.edu/upperair/sounding.html of the University of Wyoming, College of Engineering, Department of Atmospheric Science. Parts of the work underlying this publication were funded by LMU Munich’s Institutional Strategy “LMUexcellent” within the framework of the German Excellence Initiative.

Figure 1. Squared water vapor transmission between the surface and 1 km (red) and 10 km (green) in the spectral range between 904 and 916 nm, mid-latitude summer conditions. For demonstration two Gaussian emission curves with $\Delta \lambda = 2$ nm (black, solid line) and $\Delta \lambda = 4$ nm (black, dashed) are shown, $\lambda_0 = 910$ nm.
Figure 2. Effective water vapor absorption coefficient $\alpha_{w,\text{eff}}$ in the lowermost layer (0–1 km) for 6 standard atmospheres: subarctic winter (red), mid-latitude winter (blue), US-Standard (black), subarctic summer (green), mid-latitude summer (yellow), and tropical (pink). The different $\Delta \lambda$ (2.5 to 4 nm in steps of 0.5 nm) of the laser can be distinguished by the symbols. The dashed line gives the average over the spectral range from 908 to 918 nm.
Figure 3. Vertical profile of the water vapor absorption cross section $\sigma_w(\lambda, z)$: average over 647 atmospheric profiles (black), one standard deviation from the average (green), median (blue) and 10 and 90 % percentile (pink). The wavelength is $\lambda = 908.957 \text{ nm}$ (left panel) and $\lambda = 905.885 \text{ nm}$ (right panel), respectively. $\sigma_w$ is given in $10^{-22} \text{ cm}^2$ (left) and $10^{-25} \text{ cm}^2$ (right).
Figure 4. Deviation of the approximative squared transmissions \( T_{\text{eff,prx}}^2(t, z) \) from the reference case expressed in terms of the function \( G(t, z) \): average over 636 cases (black), \( G_{50}(z) \) (blue), \( G_{10}(z) \) and \( G_{90}(z) \) percentile (red), and the minimum and maximum values (green). The emission spectrum of the laser diode is defined by \( \lambda = 905 \text{ nm} \) and \( \Delta \lambda = 3.5 \text{ nm} \). The three panels (from left to right) are for different spectral resolutions of \( \Delta \tilde{\nu} = 0.1, 0.3, \) and \( 0.5 \text{ cm}^{-1} \).
Figure 5. Same as Fig. 3 but $\overline{\sigma_w}(\lambda, z)$ as derived from radiosonde data of Acapulco, Mexico.
**Figure 6.** Deviation of the approximative squared transmissions $T_{w,\text{eff, prx}}^2(t_i, z)$ from the reference case expressed in terms of the function $G(t_i, z)$ when $\sigma_w$ as derived for Oberschleißheim is used for Acapulco’s water vapor distribution (left panel) and vice versa (right panel): average over all radiosonde ascents (black), $G_{50}(z)$ (blue), $G_{10}(z)$ and $G_{90}(z)$ percentile (red), and the minimum and maximum values (green). The emission spectrum of the laser diode is defined by $\lambda=912$ nm and $\Delta\lambda=3.5$ nm. The spectral resolution is $\Delta\tilde{\nu} = 0.1$ cm$^{-1}$. 
Figure 7. Left panel: range corrected signal $P z^2$ of the CL51 (black) of 17 March 2012, 02:00–04:00 UTC (Munich, Germany). The coincident profile of the CHM15kx is shown in green, the red dashed curve is a hypothetical Rayleigh-signal at 1064 nm. All signals in arbitrary units. Right panel: profiles of relative humidity $f_{rel}$ (in %, black) and water vapor number density $n_w$ (in $10^{23}$ m$^{-3}$, blue) from the radiosonde of Oberschleißheim.
**Figure 8.** Retrieved particle backscatter coefficient at $\lambda_0 = 907\,\text{nm}$ (left) and $912\,\text{nm}$ (right) in $\text{km}^{-1}\,\text{sr}^{-1}$: $\beta_p$ with (green) and $\beta_p^*$ without (red) water vapor correction. The water vapor distribution of 17 March 2012 is assumed.
Figure 9. Ratio of the retrieved $\beta_p^*$ when water vapor absorption is ignored and the correct $\beta_p$ for different central wavelengths $\lambda_0$ of the emission spectrum: 905 (black), 908 (red), 911 (green), 914 nm (blue). The horizontal lines illustrate the uncertainties range due to wrong assumptions of $\lambda_0$ by $\pm$ 2 nm. The long dashed line refers to the “clear” case, the short dashed line to the “turbid” case, both at 905 nm (conditions of 17 March 2012).
Figure 10. Same as Fig. 8 but application of the backward integration.
Figure 11. Same as Fig. 9 but application of the backward algorithm.
Figure 12. Ratio $\beta_p^*/\beta_p$ for 4 wavelengths $\lambda_0$, when the forward algorithm is applied: 905 (black), 908 (red), 911 (green), 914 nm (blue). The solid and dashed lines are the annual average (year 2013) for Oberschleißheim and Acapulco, respectively. The horizontal lines indicate the standard deviation.
**Figure 13.** Same as Fig. 12 but application of the backward algorithm.
