Abstract. Goal of the project CARIBIC (Civil Aircraft for the Regular Investigation of the atmosphere Based on an Instrumented Container) is to carry out regular and detailed observations of atmospheric composition (particles and gases) at cruising altitudes of passenger aircraft, i.e. at 9 – 12 km. Mercury has been measured since May 2005 by a modified Tekran instrument (Tekran-Analyzer Model 2537 A, Tekran Inc., Toronto, Canada) during monthly intercontinental flights between Europe and South and North America.
America, Africa and Asia. Here we describe the instrument modifications, the post-flight processing of the raw Tekran signal, and the speciation experiments.

1 Introduction

The biogeochemical cycle of mercury has attracted much interest because of the bioaccumulation of the highly neurotoxic methyl mercury in the aquatic nutritional chain to concentrations harmful for humans and animals (e.g. Mergler et al., 2007; Scheuhammer et al., 2007; Lindberg et al., 2007, and references therein). The concern about adverse environmental impacts of mercury prompted the United Nations Environment Programme (UNEP) to undertake a global assessment of mercury and its compounds in the environment which resulted in the Minamata Convention on Mercury (www.mercuryconvention.org) in 2013.

The atmospheric mercury cycle, responsible for the worldwide transport of mercury and its deposition, is still not well understood despite more than 30 year of intensive research (e.g. Lin et al., 2006; Lindberg et al., 2007; Slemr et al., 2011). Mercury is released into the atmosphere by natural processes, such as emissions from volcanoes, and anthropogenic processes, such as coal burning and ore processing (Pirrone et al., 2010; Song et al., 2015). It is emitted as elemental vapor (gaseous elemental mercury, GEM) or as gaseous or particulate Hg\(^{2+}\) mercury compounds (gaseous oxidized mercury, GOM and particle bound mercury, PM). While estimates of global anthropogenic emissions claim a relatively modest uncertainty of 30% and less, the estimates of natural emissions and reemissions from a legacy of historical anthropogenic mercury pollution are much less certain (Pirrone et al, 2009; Mason, 2009). GOM has a short atmospheric lifetime of a few days due to its low vapor pressure and high solubility and is thus supposed to be deposited mostly near its sources (Lindberg et al., 2007). Particles carrying PM have also a short lifetime of several days. GEM, on the contrary, is almost insoluble and has a relatively high vapor pressure. Measurements of its worldwide tropospheric distribution, with a pronounced interhemispheric gradient and small gradients within the hemispheres, suggest that its atmospheric residence time is on the order of 1 year (Slemr et al., 1985). GEM thus has to be oxidized to GOM and PM for removal from the atmosphere. Three mechanisms to oxidize elemental mercury to Hg\(^{2+}\) compounds have been proposed (reactions with O\(_3\), OH, and Br) but their relative contributions are still not well known (Lin et al., 2006; Lindberg et al., 2007, Hynes et al., 2009).
Due to its rather long atmospheric residence time GEM will reach the stratosphere. The information on the behavior of mercury in the upper troposphere and lower stratosphere (UT/LS) is tenuous because of lack of measurements due to instrumental limitations. Only recently, the progress in measurement techniques has enabled extensive but short term aircraft measurements of mercury distribution in the troposphere and lower stratosphere (Ebinghaus and Slemr, 2000; Friedli et al., 2003a and 2004; Banic et al., 2003; Ebinghaus et al., 2007; Radke et al., 2007; Talbot et al., 2007a and b; Swartendruber et al., 2008; Lyman and Jaffe, 2011; Brooks et al., 2014; Weigelt et al., 2015). All observations have so far shown a pronounced decrease of gaseous mercury (GEM + GOM) concentrations in the lower stratosphere (Ebinghaus et al., 2007; Radke et al., 2007; Talbot et al., 2007a; Slemr et al., 2009; Lyman and Jaffe, 2011) which implies a conversion to PM. This implication is supported by observations of high PM concentrations in the lower stratosphere but not in the upper troposphere (Murphy et al., 1998, 2006). However, the mechanism of this conversion and its importance for the atmospheric mercury cycle is not known.

Since May 2005 mercury is being measured during monthly CARIBIC (Civil Aircraft for the Regular Investigation of the Atmosphere Based on an Instrumented Container, Brenninkmeijer et al., 2007) flights. The objective of these measurements is to gain information on the worldwide distribution of mercury in the UT/LS (Slemr et al., 2009) and on mercury emissions from biomass burning and other sources (Ebinghaus et al., 2007; Slemr et al., 2014). Here we describe the mercury instrumentation, present a method for post-flight data processing, and discuss the results of several speciation experiments.

2 The CARIBIC container

Since December 2004 a new CARIBIC container (Brenninkmeijer et al., 2007; www.caribic-atmospheric.com) onboard a Lufthansa Airbus A340-600 is being flown monthly on intercontinental flights. The routes of the flights starting in Frankfurt or Munich with destinations in North and South America, Africa, East and South Asia can be found at www.caribic-atmospheric.com. Typically, a sequence of 4 individual flights is flown every month. A modified freight container holds automated analyzers for gaseous mercury, CO, O₃, NO, NOy, CO₂, total and gaseous water vapor, oxygenated organic compounds, and fine particles (three counters for particles with diameters > 4 nm, > 12 nm, and > 18 nm), as well as one optical particle size spectrometer for particles with diameters > 140 nm. In addition, air and...
aerosol particle samples are taken and analyzed after the flight for greenhouse gases, halocarbons, hydrocarbons, and particle elemental composition and morphology (Brenninkmeijer et al., 2007). Between the end of 2009 and the beginning of 2010 several instruments were replaced by improved ones and new instruments were added. In the context of this paper the most important changes are the replacement of the malfunctioning optical particle size spectrometer (OPSS) and the addition of a whole air sampler with a capacity of 88 samples. The improved and extended instrumentation is in use since May 2010. In summer 2014, a single particle soot photometer (SP2) instrument was added.

The inlet system with four separate inlets for aerosols, trace gases, total water, and gaseous water and the container plumbing are described in detail by Brenninkmeijer et al (2007) and Slemr et al. (2009). Briefly, the trace gas probe consists of a 30 mm inner diameter diffuser tube with a forward facing inlet orifice of 14 mm diameter and outlet orifice of 12 mm diameter providing an effective ram pressure of about 90-170 hPa depending on cruising altitude and speed. This ram pressure forces about 100 L min⁻¹ of ambient air through a PFA tubing (3 m long, 16 mm ID PFA lined tube) connecting the inlet and the container and 1.5 m long 16 mm ID PFA tubing within the container to the instrument manifold, all heated to ~40°C. The air sample for the mercury analyzer is taken at a flow rate of 0.5 L min⁻¹ (STP: p = 1013.25 hPa, T = 0°C) from the manifold using the 4 mm ID PFA tubing heated by the energy dissipated in the container to about 30°C. The arrangement similar to that described by Talbot et al. (2008) was optimized to transmit highly sticky HNO₃ (Neumann et al., 1999) and can thus be presumed to pass sticky GOM as well. The large flow through the trace gas diffuser tube of more than 2000 L min⁻¹ and perpendicular sampling at much smaller flow rates of about 100 L min⁻¹ discriminate against particles larger than about one micrometer diameter (50% aspiration efficiency, Baron and Willeke, 2001). But particles smaller than 0.5 µm will pass into the manifold in the container.

The separate aerosol inlet is designed to obtain representative aerosol sampling characteristics at cruising speeds of nominally 250 m s⁻¹ and is described in detail by Brenninkmeijer et al. (2007). It essentially consists of a heated shroud, which makes the aerosol sampling characteristics largely independent of flight conditions (angle of attack), and of an aerosol diffuser tube, which slows down the air flow to velocities comparable to those in the tubing connecting the aerosol inlet with the aerosol instruments. Because the sampled air is heated from an ambient temperature of ~-50°C to ~+30°C in the container, water and...
semivolatile compounds such as ammonium nitrate, organics, and some mercury compounds will evaporate.

3 Mercury instrument and its modifications

The mercury instrument is based on an automated dual channel, single amalgamation, cold vapor atomic fluorescence analyzer (Tekran-Analyzer Model 2537 A, Tekran Inc., Toronto, Canada) and its flow scheme is shown in Figure 1. The instrument features two gold cartridges. While one is adsorbing mercury during a sampling period, the other is being thermally desorbed using argon as carrier gas. Mercury is detected using cold vapor atomic fluorescence spectroscopy (CVAFS) which responds only to gaseous elemental mercury (GEM). However, mercury compounds collected by the gold cartridge were found to be converted to elemental mercury probably during the thermodesorption and will thus be detected as well (Slemr et al., 1978). The functions of the cartridges are then interchanged, allowing continuous sampling of the incoming air stream.

After switching on the instrument the sampling lines are flushed for 240 s with ambient air made mercury free by an activated charcoal filter (carbon filter in Fig. 1). After that the instrument changes to measurement mode. The sample air is directed either directly to the gold cartridges or via a quartz wool trap (15 cm long and 2 cm diameter quartz glass tube packed with approx. 5 g cleaned quartz wool). Lyman and Jaffe (2012) showed that a quartz wool trap removes GOM and aerosol particles (i.e. PM) but no GEM. Therefore, the CARIBIC mercury analyzer can measure only GEM with the trap or GEM + GOM + PM (PM measurement capability will be discussed in Section 6) without it. On flights from Germany to a certain destination GEM is measured and on the return flights total mercury (TM = GEM + GOM + PM). A 45 mm diameter PTFE pre-filter (pore size 0.2 µm) protects the sampling cartridges against contamination by particles which pass through the inlet system. To ensure a proper sample air flow of 0.5 L min⁻¹ (STP) even at a flight level of 12 km (200 hPa) a second diaphragm pump (Neuberger Model KNF UN89 KTDC) was installed at the inlet of the instrument until May 2011. It was tested for contamination and losses of mercury and none were found. Since June 2011 this pump has been moved downstream of the original internal Tekran pump as shown in Figure 1. The pumping speed of both pumps is controlled by the flow meter. A buffer volume between the valve and the flow meter reduces the pump induced pressure.
oscillation which might bias the flow meter reading. If the instrument is switched off, the valve between the volume and the pump is closed to ensure that no air is pulled through the mercury analyzer to the other CARIBIC instruments. To avoid a contamination of the instrument and of the tubing connecting the sampling manifold with the instrument during ascents and descents in heavily polluted areas near most of the larger airports, the sampling pumps are switched on only at ambient pressure below 500 hPa. Consequently, only measurements above an altitude of about 5 km are available.

With changing flight level the pressure in the aircraft cargo bay and thereby the pressure in the CVAFS detector cell changes. As the response signal of the CVAFS is pressure dependent (Ebinghaus and Slemr, 2000; Talbot et al., 2007) we keep the pressure in the detection cell constant using a pressure controller (Bronkhorst EL-PRESS P-702CV) downstream of the detection cell. The pressure controller was set to a constant upstream pressure value of 1013 hPa.

A data acquisition computer was added to the Tekran instrument to control the instrument, to record data from the instrument, as well as from the additional sensors (pressure, temperature, valve position), and to communicate with the CARIBIC master computer which controls the operation of all instruments in the container. Initially we used a data acquisition computer (DAQ; ICP COM 7188) which, unfortunately, was too slow to record both the Tekran internally processed data and its so-called “raw data dump” output (raw detector signal with 10 Hz resolution). In February 2014 we replaced the computer by a CompactRIO DAQ (National Instruments). Since then the recorded raw data dump signal allows us to view and process it after the monthly flight sequence, as described in Section 4.

Including all components the modified instrument has a total weight of 36 kg. The power consumption in measure mode is 300 W. The instrument meets the DO160-E limits on emitted and conducted electromagnetic radiation which is required for the certification of the instrument for operation onboard passenger aircrafts.

To reduce the number of high pressure cylinders in the container, the instrument was initially operated with a gas mixture of 0.25 % CO₂ in argon used also as an operating gas for the CO instrument. As the addition of CO₂ to argon reduced the sensitivity of the fluorescence detector by quenching by ~35%, the instrument was run initially with 15 min sampling time (corresponding to ~ 225 km flying distance) until March 2006.
and with 10 min until June 2007. Since August 2007 CO$_2$ is removed from argon by an adsorber filled with X10 molecular sieve. The corresponding sensitivity gain enabled us to run the instrument with 5 min sampling (corresponding to ~75 km flying distance). To improve the detection limit and the precision of the measurements we returned to 10 min sampling in the flights between August 2011 and January 2014.

Since February 2014 the instrument has been run again with 5 min resolution. All mercury concentrations are reported here in ng Hg m$^{-3}$ (STP, i.e. 1013.25 hPa and 273.15 K).

The instrument is calibrated after every other monthly flight sequence by comparing its ambient air measurements in the laboratory with simultaneous measurements by a reference Tekran instrument. The reference instrument has an internal permeations source whose permeation rate is determined by injections of known mercury amounts every year. Calibration during the flight using the internal permutation device was not attempted because unavoidable power and carrier gas flow interruptions and ambient pressure changes prevent reaching a stable permeation rate.

Talbot et al. (2008) tentatively ascribe their measurements made with a similar inlet system and the Tekran instrument to elemental mercury only. They believe that their inlet system which transmits very sticky HNO$_3$ will also transmit GOM. But they are not sure about the response of Tekran instrument to GOM. The response of the amalgamation technique to HgCl$_2$ was verified a long time ago (Slemr et al., 1979) by coupling it to an atomic absorption detector which responds only to Hg$^0$ (GEM) and to a microwave plasma atomic emission detector which responds to mercury irrespective of the compound (Slemr et al., 1978). HgCl$_2$ was adsorbed by gold and other precious metal collectors, thermodesorbed, and detected quantitatively by both detectors suggesting that it is quantitatively transformed to Hg$^0$ either during the adsorption or more likely during the thermal desorption (Slemr et al., 1979). If all GOM compounds behave as HgCl$_2$ and GOM makes it to the gold traps inside of the instrument, the Tekran instruments will quantitatively measure GOM despite using an atomic fluorescence detector which as atomic absorption detector responds only to elemental mercury. Pyrolyzing of mercury compounds to GEM used by some researchers (e.g. Ambrose et al., 2013, 2015) is thus not necessary to measure GEM + GOM but helps to avoid GOM losses on the way from the pyrolyzer to the gold traps within the instrument.

4. Post-flight data processing
Even with the additionally installed diaphragm pump only about 2 L (STP) air samples were collected during 5 min sampling time at cruising altitudes of 10 – 12 km. The Tekran detector has then to analyse ~2 - 3 pg of mercury in the troposphere and less in the stratosphere. This is far below the threshold of ~10 pg needed for the optimal integration of the mercury peak by the instrument (Swartzendruber et al., 2009).

Figure 2 illustrates the problem. It shows a correct integration of a 7.3 pg peak whereas the integrals for 2.6 and 1.5 pg are substantially underestimated and the peak of 0.8 pg is not detected at all. Generally, the low signal-to-noise ratio of small peaks causes the internal default integration program to start to integrate later and to end earlier than it should, resulting in concentrations that are biased low. Swartzendruber et al. (2009) discussed several procedures to alleviate this problem such as to use different setting of the internal integration parameters and off-line peak quantification using peak height, cross-correlation of the peak centre with a calibration peak, and a longer integration. We have developed a procedure similar to the integration of gas chromatographic peaks: we display every measurement on the computer screen and correct the default integration using a cursor if we deem it necessary. With a Matlab script it takes about 1 hour to process data from an intercontinental flight (~130 measurements). The raw Tekran signal is available only since February 2014 but because of missing raw signal data for the calibration before February 2014 only the data since April 2014 (i.e. since CARIBIC flight #468) could be processed.

The uncertainty of the off-line integration is < 0.1 pg which can be also considered a detection limit. Relative to the median sampling volume of 1.7 L (STP) with 5 min sampling time during CARIBIC flights #468 – 492 (April 2014 – January 2015) concentrations of around 0.05 ng m⁻³ can be detected. This a substantial improvement against the instrument default integration with the detection limit of ~0.5 pg. This improvement explains why in more than 3000 measurements during flights #468-492 we have not found a single peak which could not be integrated by our off-line procedure, despite many measurements in the deep stratosphere (i.e. O₃ > 300 ppb and PV of up to 11 PVU) during the flights to San Francisco, Tokyo, and Beijing. Even the 0.8 pg peak shown in Figure 2, which was not detected by the instrument default integration, can be integrated with an uncertainty of < 0.1 pg. Thus zero concentrations occurring occasionally in our old stratospheric data and in reports by others (Talbot et al., 2007) are most likely not real but due to integration problems.
With a median sample volume of 1.7 L (STP) taken within 5 min sampling time and a median mercury concentration of 1.2 ng m\(^{-3}\) during the flights #468 – 492 the median loads are about 2 pg. The typical precision of the off-line processed data is thus \(\sim 5\%\), i.e. \(\sim 0.06\) ng m\(^{-3}\). The precision of the tropospheric measurements for flights before April 2014 employing the instrument default integration only is \(\sim 25\%\) and \(\sim 13\%\) with 5 and 10 min sampling time, respectively. As mentioned earlier the instrument was run with Ar + CO\(_2\) mixture until June 2007 which reduced the detector sensitivity by \(\sim 35\%\). The precision of these measurements is \(\sim 20\%\) and \(\sim 13\%\) with sampling times of 10 and 15 min, respectively. With lower concentrations in the stratosphere, the precision becomes worse.

Simultaneous default and off-line integration during the flights #468 – 492 allow us to assess the data quality for the earlier flights until #467 (February 2014). Figure 3a displays the ratio of off-line processed (new) to default integrated (old) concentrations as a function of the old mercury loads \(> 0.5\) pg for the measurements during flights #468 – 492. The ratio is almost always larger than 1 and increases with decreasing mercury load. That means that the old measurements are mostly biased low. An alternative plot of the ratio of new to old concentrations vs. new mercury load (not shown) shows a nearly linear inverse function of the new, i.e. the real mercury load below \(\sim 8\) pg and a ratio of 1 above \(\sim 8\) pg. Figure 3b shows the binned data from Figure 3a and a function derived from them which we used for the correction of the bias of old loads \(> 1\) pg in the data base until flight #467, i.e. for all CARIBIC flights between May 2005 and February 2014. A correction function encompassing even smaller old loads led to unrealistically high correction for old loads in the range of 5 – 15 pg which are not biased. In addition, the larger the correction is, the less credible it becomes and occasionally occurring zero old loads cannot be corrected at all. By limiting the correction to old loads \(> 1\) pg we essentially remove the bias of all old tropospheric and some stratospheric measurements near to the tropopause. Measurements deeper in the stratosphere are irretrievably lost. We note also that by applying the correction we remove only the bias but do not improve the precision of the old data which we estimate to be \(\sim 0.2 – 0.3\) ng m\(^{-3}\). The corrected old tropospheric data from flights #468 – 492 (flights with both new and old data) deviated on average by 3% from the corresponding off-line processed concentrations. This gives us confidence in the correction and homogenization of the old tropospheric data. A homogenization is needed e.g. for trend investigations...
because the varying sampling times and the resulting varying mercury loads led to varying low biases between May 2005 and February 2014.

We would like to point out that the problem with integration of sub-optimal sample loads does also apply for a large part of GOM and PM measurements reported in the literature. Most of these measurements are made by an automated Tekran method (Tekran 2537/1130/1135 system, e.g. Gay et al., 2013). The system is typically run with 2 h sampling of GOM and PM at a flow rate of 10 L min⁻¹ (STP) each, yielding sample volumes of 1.2 m³ (STP). Average GOM and PM concentrations of ~2 and ~4 pg m⁻³ (Gay et al., 2013), respectively, provide mercury loads of ~2.4 and ~4.8 pg which are well below 10 pg needed for the default bias-free integration of the peaks. To the best of our knowledge, the underestimation of GOM and PM concentrations caused by the integration of the sub-optimal Hg loads has not been considered in discussions of the GOM and PM measurement accuracy so far (e.g. Gustin et al., 2013, 2015).

5 Aerosol collection and mercury analysis by PIXE

The aerosols sampled through the aerosol inlet are collected by a multi-channel aerosol sampler described in detail by Nguyen et al. (2006). The sampler operates using the impaction technique at a flow rate of 10.4 L min⁻¹ and has 16 sampling channels. Each channel contains two sample types: one is used for quantitative analysis of aerosol element composition using particle-induced X-ray emission (PIXE) and the one for single particle morphology investigation using electron microscopy. The sampler is loaded with sampling substrates to cover both the outbound and the return flights. Fourteen channels are used for sequential sampling and the remaining two channels are open during the entire outbound or return flight (integral samples). The detection limit of PIXE analyses for mercury is ~0.2 ng m⁻³.

So far we have not detected any PM above the detection limit of the PIXE analyses, neither in tropospheric nor in stratospheric aerosol samples collected during the CARIBIC flights. This appears to be in contradiction with the observations of Murphy et al. (2006) who report high PM concentrations in the stratosphere while they could hardly detect any PM in the troposphere. Based on assumptions about the Hg ionization efficiency of their Particle Analysis by Laser Mass Spectrometry (PALMS) instrument, which was not calibrated, they estimate that PM constitutes 5 – 100% of all mercury in the LS. There are three possible explanations for this contradiction: 1. the concentrations of PM observed by Murphy et al. (2006)
are below the PIXE detection limit, 2. PM compounds are semivolatile and evaporate either in the aerosol sampling inlet (Section 2) and the tubing connecting the inlet and the aerosol sampler or 3. during the PIXE analysis in the vacuum.

Murphy et al. (2006) could not detect any PM in particles at lower altitudes in the troposphere (~ 7 km below the tropopause, i.e. ~ 5 km above the ground). Consequently, the free tropospheric PM concentrations at this altitude represent the lower limit of the PALMS sensitivity. PM vertical profiles were measured only recently (Brooks et al., 2014). Although measurements in July, August and September are missing, the data show a pronounced seasonal variation with minimum PM concentrations in winter months. Most of the measurements by Murphy et al. (2006) were made in spring and summer, and the corresponding PM concentrations reported by Brooks et al. (2014) for the altitude range of 4 – 6 km varied between ~20 and 110 pg m⁻³. With a sample volume of 300 L the low concentrations of 20 pg m⁻³ are probably biased low because of integration problems described in Section 4. Thus the PALMS lower detection limit represents ~ 2 – 10% of total mercury concentration of ~ 1 ng m⁻³ at the tropopause which is consistent with the lower estimate by Murphy et al. (2006) for the PM fraction of the total mercury concentration.

Another possibility to assess the PM concentrations measured by Murphy et al. (2006) are the recent measurements of oxidized mercury in the UT/LS (Lyman and Jaffe, 2012; Brooks et al., 2014; Shah et al., 2015). Lyman and Jaffe’s measurements suggest that Hg²⁺ represents more than ~90% of total mercury above the tropopause. Brooks et al. report spring and summer GOM concentrations of 30 – 80 pg m⁻³ in the altitude range of 5 – 7 km above ground, but these measurements might be biased low by a factor of 3 (Gustin et al., 2013; 2015). Shah et al. (2015) report unbiased average Hg³⁺ concentrations of ~ 200 pg m⁻³ in the altitude range of 6 – 7 km in summer. Taking the bias in measurements of Brooks et al. (2014) into account, their measurements are consistent with those of Shah et al. (2015). Hg²⁺ compounds are semivolatile and will readily attach to particles at low temperatures near the tropopause and above it.

Rutter and Schauer (2007) measured the gas-particle partitioning coefficients for HgCl₂ as a proxy compound for Hg²⁺ on different types of particles within a rather narrow temperature range of ca 270 – 303 K and Amos et al. (2012) derived them from GOM and PM observations in the planetary boundary layer. If these partitioning coefficients are extrapolated to a tropopause temperature of ~ 230 K and taking into
account a median particle mass concentration during the CARIBIC flights of 0.6 µg m\(^{-3}\) (STP) at least 70% of GOM should be attached to particles. Consequently, GOM concentrations of 200 pg m\(^{-3}\) observed by Shah et al. (2015) at 6 – 7 km altitude and much higher GOM concentrations expected at higher altitudes (Lyman and Jaffe, 2012) imply PM concentrations at and above the PIXE detection limit. Our inability to see any PM by PIXE thus suggests that PM likely evaporates either during the sampling or during the PIXE analysis in vacuum. We are aware that extrapolation of partitioning coefficient from the narrow range of measured temperatures might be fraught with substantial error. Measurements of partitioning coefficients over a larger temperature range are needed.

The above considerations have also implications for the GEM and GOM measurements via the trace gas inlet. The temperature within the container varies between 30 - 40°C. With GOM/PM equilibria determined by Rutter and Schauer (2007) and Amos et al. (2012), almost all PM will evaporate to GOM during the transport from the trace gas inlet to the Tekran instrument and will be measured as such.

Based on the above discussion, our measurements will in addition to all gaseous mercury also likely encompass mercury evaporated from the particles which pass through the CARIBIC trace gas inlet. We calculate that particles with diameter < 0.5 µm will pass through the trace gas inlet described by Brenninkmeijer et al. (2007), representing ~ 70% of the particle mass in the UT and LS. Hg\(^{2+}\) formed by photochemical processes will be attached to particles proportionally to their surface area which is dominated by smaller particles. Consequently, 70% of particulate mercury represents the lower limit for the mercury on particles which will be co-determined by our system.

6 Speciation experiments and their interpretation

The speciation experiments onboard the CARIBIC container are restricted by the certification procedures which allow only small internal instrument modifications without any safety relevance. A dedicated external speciation unit is thus no option. Within these limitations we added a GOM scrubber upstream of one of the two gold collectors or upstream of both gold collectors during the outbound flights as shown in Figure 1. In the initial experiments we run the instrument alternately in a mode without and with the scrubber (5 min with and 5 min without). The experiments in March – June 2008 were carried out with the commercially available soda lime trap (Tekran part # 90-13310-06). Despite the careful cleaning of the
soda lime trap before the monthly flight sequence, mercury concentrations measured by the channel with soda lime trap were higher than those measured by the channel without the trap at the beginning of each individual flight. The difference disappeared within about 1 - 2 flight hours. It seems that soda lime contains traces of mercury which diffuses slowly and continuously from the bulk of the material to its surface and accumulates in the time before the flight sequence and between the individual flights when the trap is not flushed by the sample air. After switching on the pumps it is slowly flushed away. Because of this sort of mercury bleeding the soda lime trap was abandoned and replaced during the flights in March and April 2009 by a trap of the same size filled with quartz sand coated by KCl. Both traps were tested for quantitative transmission of elemental mercury before inserting them into the instrument. Since August 2014 (flight #472) we use a quartz wool trap described by Lyman and Jaffe (2012). The air is directed through the trap during the outward flight and bypasses the trap during the return flight (see Fig. 1 and associated description).

We are aware of the problems frequently encountered with GOM (and PM) traps such as interference of KCl surface with ozone and humidity (e.g. Lyman et al., 2010; Gustin et al., 2013; Huang et al., 2013; Huang and Gustin, 2015). Quartz wool traps are claimed not to be influenced by ozone (Ambrose et al, 2013, 2015) but can release GOM in humid air. This should not pose a problem in the UT/LS with very low absolute humidity. Because of these problems we discuss the results of the trap experiments mostly only in qualitative terms.

After an initial flushing effect described above, the experiments with soda lime trap showed generally smaller mercury concentrations with the trap than without it. The difference between the concentrations without (TGM) and with the trap (GEM if the trap removes GOM quantitatively) tended to be larger in the stratosphere than in the troposphere. These results are consistent with the speciation measurements of Lyman and Jaffe (2012) and demonstrate qualitatively that GOM is transmitted through the inlet and the tubing into the instrument.

This conclusion is supported by the experiments with the KCl trap. It was deployed in March 2009 during the flight sequence Frankfurt -> Cape Town -> Frankfurt -> Orlando -> Frankfurt (CARIBIC flights #262-265) and in April 2009 during the flight sequence Frankfurt -> Caracas -> Frankfurt -> Vancouver - >
Frankfurt (flights #266-269). Both flight sequences were of the same duration (~ 36 h) but the stratospheric section of the flights in March was with a total of ~ 9 h much smaller than in April with a total of ~ 21 h. The KCl trap was analyzed for its mercury content after each flight sequence and 50 pg of mercury were found after the flights in March, with an uncertainty of ~ ±10 pg. The total sampling volume during the flights in March was 500 L (STP) resulting in an average GOM concentration of ~0.1 ng m\(^{-3}\). 57 ± 10 pg of mercury were found on the KCL trap after the April 2009 flight sequence. With an overall sampling volume of 450 L (STP) it suggests an average GOM concentration of ~0.13 ng m\(^{-3}\). This concentration is somewhat larger in accordance with the longer time spent in the stratosphere although not proportional to it. Mercury found on the KCl traps again shows that GOM is transmitted through the inlet and the tubing to the instrument.

During the flight #269 (April 2009) from Vancouver to Frankfurt the aircraft flew almost always in the deep stratosphere (on average ~ 7 PVU, ~550 ppb O\(_3\), CO below 30 ppb). TGM concentration remained with 0.3 ng m\(^{-3}\) nearly constant while the difference between the channel without and with the trap varied between zero and 0.3 ng m\(^{-3}\). None of the simultaneously measured parameters provided a hint on what this variation might have depended on. But the same concentrations of total gaseous mercury and its complete removal by the trap during some sections of the flight suggest that all gaseous mercury was oxidized. In addition, the constant TGM over large parts of this flight with GOM varying from nearly zero concentration to concentrations comparable to TGM suggests that the GOM transmission by the inlet tubing is nearly quantitative.

Figure 4 shows mercury concentrations as a function of simultaneously measured ozone mixing ratios measured during the outbound flight from Munich to San Francisco (flight #476) on September 23, 2014, and the return flight on September 24, 2014 (flight #477). Sample air was directed through the quartz wool trap during the outbound flight and these measurements are denoted as GEM. During the return flight the quartz wool trap was bypassed and the sample air was fed directly into the instrument and these measurements are denoted as TGM. A direct GEM vs. TGM comparison is not possible because of the differences in flight track and flight altitude. In the troposphere at O\(_3\) < 100 ppb GEM and TGM concentration tend to be comparable whereas TGM concentrations tend to be larger than GEM at O\(_3\) > 200 ppb, i.e. in the stratosphere.
In summary, experiments with all three trap types demonstrate clearly that GOM is transmitted by the inlet tubing to the instrument. The tendency for higher GOM concentrations in the stratospheric sections of the flights further supports this evidence. The equal concentrations of TGM and GOM during some sections of flight #269 suggest that all gaseous mercury was transformed to GOM and that the transmission might be nearly quantitative. Our findings are consistent with Temme et al. (2003) who found that GOM is transmitted quantitatively by PFA tubing at low temperatures and humidities encountered in Antarctica, conditions similar to those encountered during the CARIBIC flights at cruise altitude. Quantitative GOM transmission by the CARIBIC inlet can also be expected because the inlet tubing was constructed and operated at conditions which are known to transmit HNO₃, one of the stickiest compounds known to atmospheric chemists (Neuman et al., 1999; Talbot et al., 2008). Finally, the inlet described by Lyman and Jaffe (2012) with demonstrated GOM transmission is also very similar to the CARIBIC inlet. Despite all this evidence for quantitative transmission of GOM to the instrument we cannot prove it by measurements. One reason is the lack of devices producing GOM test mixtures (Lyman and Jaffe, 2012). But even with recently developed devices for GOM test mixture generation (Huang et al., 2013; Ambrose et al., 2015) we will not be able to replicate the sampling conditions during the flight. We have to wait for in-flight comparison with an aircraft with proven GOM measurement capability.

In summary, we believe that the mercury concentrations measured by the instrument in the CARIBIC container represent all gaseous elemental and oxidized mercury, and at least 70% of particulate mercury depending on its particle size distribution. In the troposphere, where particulate mercury constitutes usually less than a few percent of gaseous mercury, our measurement will approximate total mercury (TM).

7 Conclusions

The instrument described here has been onboard the CARIBIC container since May 2005 and provided mercury data for more than 98% of the flight time. With this data availability it belongs to the most reliable instruments in the container. Unfortunately, the Tekran raw signal became available only since April 2014. Using a Matlab script we demonstrated the necessity of the post-flight off-line integration of the raw signal to get bias-free and more precise data. In addition, no zero mercury concentrations have been detected since the implementation of the post-flight integration of the raw Tekran signal. From simultaneous Tekran...
default and post-flight integrated data from flights made between April 2014 and January 2015 we derived a function which enabled us to remove the low bias of the old tropospheric data until February 2014. The larger part of the stratospheric data until February 2014, however, is lost. We would like to emphasize that the problem with the biased integration of small mercury loads (< ~ 10 pg) also applies for a large part of GOM and PM concentrations reported in the literature. To the best of our knowledge, the low bias of GOM and PM concentrations caused by the biased integrations of small mercury amounts have not been discussed so far (e.g. Gustin et al., 2013, 2015).

Speciation experiments demonstrated qualitatively that GOM is transmitted through the inlet system to the instrument and will be measured together with GEM. However, due to limitations given by the use of a passenger aircraft the proof of quantitative GOM transmission is feasible only by an in-flight intercomparison using a research aircraft with proven GOM measurement capabilities. Based on existing experience with sticky HNO$_3$ we believe that GOM is sampled and measured quantitatively.

Particles are also collected onboard CARIBIC using a separate aerosol inlet and an impactor sampling device. No PM could be found on aerosol samples by PIXE analyses with a detection limit of 0.2 ng m$^{-3}$ for mercury. Our inability to detect PM by PIXE in the LS despite of high PM concentrations reported by Murphy et al. (2006) suggests that PM has evaporated either during the sampling or the PIXE analysis in vacuum. PM/GOM partitioning coefficients measured within a narrow range around 20°C and extrapolated to temperatures encountered at the tropopause suggest that most Hg$^{2+}$ will be GOM at container temperature and PM at tropopause temperature. Evaporation of PM to GOM during the sampling is thus quite probable.

If PM on particles which make it through the trace gas inlet into the instrument manifold evaporates during the transport from the inlet to the instrument it will be measured as GOM. At flight conditions particles with a diameter < 0.5 µm will pass through the trace gas inlet representing ~ 70% of the aerosol mass. As GOM will be preferably attached to smaller particles this is the lower limit of particulate mercury which will be measured together with the gaseous mercury (GEM + GOM). In summary, we believe that the CARIBIC instrument provides mercury data which approximate total mercury content of the sampled air including mercury on particles.
Acknowledgments

We would like to thank Lufthansa and all members of the CARIBIC team for their continued effort to keep running such a complex project. We thank especially Dieter Scharffe, Claus Koeppel, Stefan Weber, and Torsten Gehrlein for the day-to-day maintenance and operation of the CARIBIC container. Funding from the European Community within the GMOS (Global Mercury Observation System) project and from Fraport AG is thankfully acknowledged.
