From reviewer #1, "Because the paper focuses on determination of ramp dimensions using VA method, this Ms must... say something about the ramp period. Otherwise, a reader has the feeling that the Ms is incomplete.... the present Ms must to add a sentence about the ramp period. In fact, I do not understand why it was not included because after determination of the ramp amplitude and the time lag that peaks S3r/r the calculation of the ramp period is straightforward using VA. Thus, no extra figures or calculations must be implemented." I have added a more complete description of the SR calculation of flux, including the determination of the ramp period (tau) as it relates to computation efficiency. I have also reordered some of the method description to be more pertinent to the surface renewal method in particular.

Also from Reviewer #1, "Because the authors mentioned that there is a companion paper where they compared (I guess) SR and EC fluxes, one may hesitate the latter issue was addressed in the forthcoming Ms. I have clarified that the experiment alluded to in the manuscript does calibrate surface renewal flux on the basis of fluxes calculated via eddy covariance."
From Reviewer #2, "I am eager to try the supplemental code over my own data." I have updated the manuscript with a declaration of data availability (with a DOI), and listed the URL from which data and complete code can be downloaded. "Some clarification will be necessary in parts of the manuscript." I have made some attempt to identify some ambiguous references and clarify these, expecting that the discussion forum will raise additional needed clarifications. "Also, very important comment on possibility to use this computationally efficient approach in dataloggers programming for online flux computation is needed in more detailed discussion." While this is a research interest that will be pursued, no attempt has been made to date to implement such computational approaches in a data logger programming language. Nonetheless, it should be straightforward to program the most relevant aspects of these techniques in languages that are pre-compiled with methods such as the FFT (for example, Campbell Scientific loggers using CRBasic). The authors will attempt to address this in the discussion forum, as it is not a task that has actually been completed to date.
GENERAL COMMENTS:
The authors gratefully acknowledge the reviewer's comments, which have led to substantial changes in the manuscript, which was initially revised in May 2017, and again recently in response to additional review. Overall, I have attempted to improve clarity of writing; specifically, the hypotheses and goals of the manuscript have been clarified, and the methods are more clearly delineated with appropriate and up to date citations. The brief conclusion has been changed to be more appropriate, in particular to describe additional results which have been included in response to additional reviewer requests. The most significant of these was expanding on actual implementation of despiking via convolution, using a phase space criteria for quantitative spike identification. I have also attempted to clarify those parts of the analysis which are novel in implementation, within the context of previous work in programmatic algorithms.
Specific comments are addressed in the supplementary notes, attached.

SPECIFIC COMMENTS:
P1L9: “20 Hz+” I suggest changing to “10+ Hz” since there are articles published on successful SR application over data collected at 10 Hz frequency. Similarly, it is mentioned 10+ Hz in the introduction section.
Changed as requested. Further clarifications later in the text as to different sampling frequencies and the corresponding cost in data storage and computational efficiency.

P1L13: Please add, “computational” before the word “efficiency”
Added as requested.

P1L14: Please, be more specific, i.e. avoid saying “Programming techniques such as these”, it is still not clear in the abstract what you are referring to...
This section has been re-written to be more concrete and an appropriate summary.

P1L19: Please add word “possible” between “determinations” and “using”.
Added as requested.

P2L50: Please clarify. It is said in this line that the convolution is used for structure functions computation, while later is said the convolution is used to despike the data. It seems that the convolution is used for both and should be explained.
Added clarification here as requested.

P2L51: Replace “simplifying” with “to simplify”
Replaced as requested.

P2L53: Please, start the Methods differently... it is always better for the reader to be more specific.
Changed with the intent to be more specific for the reader.

P2L59: Add, “the method” before “implementation”
Added as requested.
P4L105: Please change the word “approach” to “program” or “program run” for clarity. Changed as requested.

P4L111-113: Please rewrite for the clarity. Changed as requested.

P4L114: Please replace “identical” by “from the same 20 Hz dataset”. Replaced as requested.

P4L131 and L133: Should “N-1” be actually “N-r”? Yes, thank you for catching this error in the text.

P4L133: Should “T(t)” be “T(i)” in accordance to Eq.1. and for clarity? No, this sentence refers to the time series rather than the discrete samples, but I agree it was unclear due to proximity of the terms. It has been changed for clarity.

P5L137: “sweeps and ejections” of what? It should be clarified adding more description of the surface renewal method background. Added as requested.

P5L138: Please add “ramps in the temperature signal caused by” between “geometry of” and “coherent structures” Added as requested.

P5L140 and L141: Please change to be clearer that the detection of the structure functions in the scalar signals improved. Added discussion of the improved detection and concurrent increase in statistical robustness with larger sample sizes (higher frequency measurement)

P5L144: Explain under which conditions. Added as requested. Other reviewers noted the ambiguity of this statement so a short discussion of flux direction and atmospheric stability was added.

P5L146: Please replace “to” by “for” if I understand well. In addition, explain why are the periods of 8 hours collected, and not continuously for two months. What challenges did you find? Was it only data collection for the unstable conditions? This language was too abbreviated in the text, and has been updated to reflect that I am describing several different experiments. The description now indicates that this data was used to test the methods with different performance criteria- i.e. data of different sizes, experiment durations, and captured at different frequencies.

P5L147-L150: Please explain how this analysis is useful. Are fluxes better to be calculated for 3 minute periods? The introduction and discussion have been expanded to indicate why short duration fluxes are under consideration.
P5L163: What “total data size” means? It works with the same efficiency over 20Hz and 100Hz dataset? Please clarify.
I have attempted to clarify this characterization of "total data size".

P5L169-170: Is this the result of the authors’ own research? If not, please give a reference.
I have gone back through my results and observations and changed this statement. I believe that my original intent was to indicate the relationship between friction velocity, vertical flux rate, and ramps times, and mis-stated these observations as being related to stability. I have changed the text and added a short explanation of the rationale, which is not a novel observation (i.e. higher velocity means faster exchange rates).

P6L174: “again the largest factor in the difference between two methods” is making this phrase unclear. Please change to clarify.
Changed for clarity.

TECHNICAL CORRECTIONS:
P1L10: One extra space seems to be typed in between the words “demonstrate” and “that”
P1L26: I think “manifests” is necessary instead of “manifest”
P2L60: “on” instead of “one”
P3L95: “an” instead of “a” before “application”
P4L111: Please use different word instead of “conditioning” if possible (i.e. “despiking”)
P4L135: Please replace “product of” instead “product by”?
P5L165 and 166: are empty.
Avoid “@” in Figure titles.
These technical corrections are appreciated and have been addressed.

P4L135: Please replace “sense” by “importance in the flux measurement” or similar. Also, replace “generate” by “are”
The language has been changed for clarity. In particular, the word "sense" was used to indicate vector direction.

P5L158: Please replace “difference vectors” by “the vectors of the differences”. In addition, change “for each sample lag” by “for the corresponding sample lag”
This has been changed for clarity as suggested.
General comments from Reviewer #3:
These comments made by this reviewer have helped to make significant improvements in the revised manuscript. In particular, I was unaware of the review of despiking methods by Starkenburg et al. (2016), and this citation has significantly improved the context of this research and has helped narrow the discussion of the intent of my manuscript, and clarify what the novel aspects of the methods described here. Also, the reviewers prompted me to re-read of French et al.’s 2012 publication using the SR method, and the discussion of lag time there has helped improve my discussion of practical aspects of computation. Following the reviewers suggestions, I have re-written the abstract, introduction, and conclusions sections to clarify the intent, context, and relevance of the three computational methods described in the manuscript.

Specific Comments:
Abstract: Logical presentation in the abstract needs improvement... What is your thesis?
I acknowledge the lack of clarity and have re-written the abstract to clarify that the intent of the paper is to document and quantify the efficiency of three algorithms, which rely on convolution and algebraic simplifications, and consequently facilitate implementation of the surface renewal method. A secondary finding of the manuscript relates the flux averaging period and computational efficiency. Mention of potential uses for this findings (open source methods, implementing SR on mobile platforms, integration into hardware solutions, etc.) and similar have been moved to the discussion in the conclusions section, rather than being misleadingly referenced in the abstract.

Not mentioned, but should be, are the SR limitations relative to EC... quantify the benefits: how much less does SR cost?
I have added discussion relating more context and citations regarding practical implementation of SR to measure flux.

What fetch benefit does one gain with SR?
Because it is relevant to the context and motivation for the SR method generally, I have added language to better cite relevant references (Castellví 2012, Göckede et al. 2004; Paw U 2005), and brief discussion regarding the measurement fetch. I have kept this limited as it is not directly relevant to the computational method. In one sense, the method's reduction of measurement fetch is not clearly established in the literature, and following Castellví (2012), it is probably comparable to eddy covariance. However, it is clearly established that SR can give reliable measurements of flux within the roughness sub-layer (Paw U et al. 1995; Katul et al. 1996; Chen et al. 1997; among others more recently). Due to this difference from eddy covariance and gradient methods which require measurements at two heights, the practical source-sink area associated with a measured flux is smaller, and spatial footprints can therefore be resolved at finer scales.

L43: a major problem here: you have yet to publish your manuscript assessing efficacy of different averaging periods, but as of now we don’t know the result and so do not know how important your algorithm refinement is.
I have expanded the description of the field experiments, and included results that quantify the improved calculation efficiency.
Regarding de-spiking: authors should read and consider findings in Starkenburg et al. 2016, with attention to their Table 1.
I am grateful for the reviewer for bringing this paper to my attention as it was published after this manuscript was originally prepared, and significantly adds to the context of the work shown here. While de-spiking is a required QAQC process with micromet data, the convolution method shown here specifically addresses and improves computational efficiency, and shows significantly improvement over the methods shown in Starkenburg’s review of published methods. In addition, the convolution approach facilitates a more sophisticated application of the phase space approach, and overcomes a major limitation of that approach through efficient calculation. I have added a brief discussion of my method to the manuscript to demonstrate the benefit of signal processing techniques like convolution.

Discussion of convolution should mention that the time-series operation includes multiplication of the time-reversed kernel.
I have added more technical description of convolution.

Regarding structure function lag estimation, consider findings reported in French et al. discussing lag vs. SR accuracy.
This citation was also a good suggestion, and I have added a brief discussion of the relevance of lag time to the methods' accuracy, and how this pertains to computational efficiency.

Root solving is not innovative although I will grant innovation in the diagnostic findings of pathological cubic equations by Edwards and Beaver. It would be useful to compare the speed improvement using Cardano's method vs. numerical Newton-Raphson.
Although I grant that this would be an interesting comparison, I think that it suffices to state that algebraic solutions are always less computational intensive than any iterative root finding algorithm. Cardano's algebraic solution requires fewer operations than any numerical root finding solution of which I am aware- it is a happy coincidence that he so-called "depressed" cubic polynomial is the one needed to solve the structure function arrangement posed by Van Atta.

If your aim is open-source you should provide readers with evidence that m script successfully executes on a non-proprietary software platform.
I agree! In the interest of time, I have not included my partial results of executing these methods in Python, which are ongoing. I rephrased this mention of potential open source implementations to my discussion as a needed action.

Line 166: here is a critical finding about computation time vs. averaging period; you should find a way to highlight this and not bury it in the text.
I agree that this is one of the coherent points in the results, and I have reworded to emphasize it.
Computational Efficiency for the Surface Renewal Method

Abstract.
Measuring surface fluxes using the surface renewal (SR) method requires a set of programmatic functions algorithms for tabulation, algebraic calculation, and data quality control. A number of different methods have been published describing automated calibration of SR parameters. Field experiments conducted over a variety of surface conditions used eddy covariance (EC) as a control flux determination for sensible heat flux and evaporation. Because the SR method requires high frequency (10 Hz+) measurements of a temperature or scalar trace concentration, some steps in the flux calculation are computationally expensive, especially when automating SR. Some implementations of SR, such as Experimental hypothesis optimization of averaging time, that require perform many iterations of these calculations. For a study on the minimum time to measure flux, To economize this type of analysis, Several new programmatic algorithms methods were written to that perform the required calculations more efficiently and rapidly, and tested for sensitivity to length of flux averaging period, ability to measure over a large range of lag time scales, and for overall computational efficiency. These algorithms utilize signal processing techniques and algebraic simplifications that demonstrating simple modifications of that methods dramatically improve computational efficiency. The results here complement efforts by other authors to standardize a robust and accurate computational SR method. Increased Programming techniques speed of computation time such as these can grants flexibility to implementing the SR method, opening new avenues for SR to be applied used in research, for applied monitoring, and in novel field deployments.

1 Background/Introduction

Originally described by Van Atta (1977), the SR model measures vertical flux that occurs during rapid events which manifest as coherent structures in a turbulent flow. The physical mechanisms are statistically distinct from those described in the Eddy eddy covariance (EC) method, which has been established as a robust and accurate method to measure flux (Baldocchi, 2014). The surface renewal (SR) method offers several advantages and complements over the use of EC to measure flux. While EC requires a high frequency (10 Hz+) measurement of both the vertical wind speed and air temperature to measure the sensible heat flux, the SR method does not explicitly require vertical wind speed, allowing can make this flux to be determined solely from rapid measurements of temperature or other scalar concentrations air temperature measurement only. By fewer, lower cost sensors are required, cost is d, which expands the SR method theoretically can be
used for direct flux measurement from research applications to more general to develop the SR method for field applications monitoring (Paw U et al., 2005; Spano et al., 2000). Another advantage of SR is over methods such as EC. Previous studies have shown that the ability to measure flux measurements can be captured very near the surface or near the top of the plant canopy using SR (Katul et al., 1996; Paw U et al., 1992). By taking measurements very close to the surface, the measurement fetch is effectively reduced and consequently the effective area from which the flux can be attributed “area footprint” or contributing area is smaller (Castellví, 2012), yielding a more localized flux estimate.

The SR method estimates turbulent transport rates from fast response measurements of scalar properties such as temperature or trace gas concentration. In the SR conceptual model, rapid changes in scalar concentration are associated with episodic displacement of near-surface air parcels, and the surface condition is renewed from upper air. While in proximity to the surface, the air parcels are gradually enriched or depleted in temperature or scalar concentration by diffusion (Castellví et al., 2002; Paw U et al., 1995). The majority of flux from the surface is attributed to these rapid ejections, which distinguish coherent structures in near surface atmospheric motions (Gao et al., 1989). The duration and amplitude of these rapid fluctuations (visible as ramps in the scalar trace) are used to determine the magnitude and direction of the flux density. As in Taylor’s concept of frozen turbulence described by, small scale turbulent transport primarily occurs in during rapid events which manifest as ramp-like coherent structures. Consequently, it should be possible to measure estimate flux over shorter periods with SR than is typical for EC (15-30 minutes). One possible use of this kind of rapid flux measurement would be to map spatially heterogeneous flux using near-surface lightweight sensors mounted on a mobile device. A mobile application of SR could provide missing information for understanding sub-basin scale hydrology, to validate downscaled models, and facilitate efficient water use through heterogeneity precision irrigation systems.

Another advantage is by reducing sensor cost, SR can allow more extensive flux measurements than can be accomplished with expensive equipment such as EC systems. By measuring extensively, the spatial heterogeneity of surface fluxes can be explored, and adding to the data collection capacity of sparsely located, regional weather networks. Lower cost sensors also facilitate measuring flux in situations where deploying more expensive equipment would be infeasible, such as direct monitoring of farm water use, at unsecured field sites, and in developing regions. Standardization of calibration and quality control measures to establish uniform methods.

Because of the short duration of these events, the SR method complements spectral methods to evaluate the flux contributions made over time scales shorter than the typical 15-30 minute averaging time used for EC (Katul et al., 2006; Shapland et al., 2012a, 2012b). Rapid flux measurement will facilitate new applications, such as spatial mapping of flux using vehicle mounted, near-surface sensors, and real-time monitoring systems. Mobile SR implementations and other novel field methods could provide new insights into the complexities of sub-basin scale hydrology, be used to validate downscaled models, and measure the heterogeneity of flux at sub-field scales.

The implementation of specific The use of SR to map heterogeneous surface flux from on to map flux requires a prescribed will first require establishing knowing the minimum averaging time period (on the order of minutes) and ramp time duration (on the order of seconds), in which SR can resolve for robust for which a representative and statistically robust flux magnitude can be determined can be obtained robustly. To implement
SR on a moving vehicle (for instance, to map spatially variable flux), finding a minimum averaging time is desirable to increase the spatial resolution of the resulting map. The averaging time and lag time used in the SR method relate the sensitivity of the scalar measurement to the time scales at which most significant flux occurs (Shapland et al., 2014). To find the minimum required measurement period, several field studies were conducted over in 2014 and -2015 over various types of surface conditions. This required a rapid computational method that worked -E, and fluxes were computed -over a range of different time averaging periods, and which could implement the various calibration procedures used in the SR method with co-located EC and SR sensors, with several different surface, weather, and crop conditions. Initial attempts to calculate flux initially, the computation followed edging the methods as described by described in Paw U et al. (2005a) and Snyder et al. (2008) literally. However, implementing these methods as documented but was hampered by slowed by computation time, which constrained the processing many required iterations required to determine the minimum flux averaging period. However, executing these methods literally as described was constrained by computationally found to be inefficient time.

As late as the 1990’s, limits on computing power, data logger memory, and telemetry limited the implementation of SR to highly skilled researchers (Katul et al., 1996; Snyder et al., 1996). Open source software and online forums are abound with methods that utilize advances in computing power, memory availability, and the accessibility of multithreaded processing when calculating over the many iterations that were required for multiple averaging periods. More efficient methods were found to utilize the increased computing power that is currently available, and to take advantage of parallel processing approaches. These approaches methods reduce computational overhead, and open possibilities to augment the for-SR technique as to allow implementation which can be a constraint when with using low cost data computers and data loggers, or where remote telemetry is required.

Three example methods are shown here which clarify streamline specific operational steps in the SR method. The first is a rapid method adapted from signal processing to “despike” noisy data, a quality control technique commonly required used to in processing raw meteorological data. Second is a method to compute structure functions over multiple time lags rapidly using convolution in two dimensions. Third, an algebraic solution array calculation is used to find the roots of a cubic polynomials roots used to which facilitates the rapid determination of SR ramp amplitude as an array calculation. By using more efficient algorithms, rapid iterative trials can be conducted to adjust calibration parameters, test hypotheses on the time averaging of flux calculations, and potentially measure SR flux in real-time.

Advantages such as low cost, relatively simple instrumentation, and easier field implementation are all cited as motivating factors to use the SR method (Paw U et al., 2005), yet work remains to standardize a robust method (French et al., 2012; Suvočarev et al., 2014). Because sensor cost is reduced, SR systems can be implemented to measure flux more extensively than EC, and in situations where EC is impractical. Extensive, site specific SR estimates can augment the utility of sparsely located, permanent weather stations in mapping the heterogeneity of surface flux. Examples of situations which could benefit from low cost flux measurements include direct crop ET monitoring, experiments at remote field sites, and in developing regions. While SR may expand flux measurement
applications, the method still requires standardized calibration and quality control measures to establish that SR is robust and accurate, and a critical step in developing the method is to reduce computation costs.

2 Methods

The example computational approaches—algorithms shown here were adapted to improve or economize existing methods, including despiking of scalar trace data series data (Højstrup, 1993; Starkenburg et al., 2016, Hojstrup, 1993; Vickers and Mahrt, 1997), calculation of structure functions (Antonia and Van Atta, 1978; Antonia and Van Atta, 1978), and Fourier analysis of signals i.e. spectral analysis (Press, 2007; Stull, 1988). In each case, dramatically faster execution times were accomplished using simple programming improvements. Most efficiency gains were due to a result of code to vectorization, which is the conversion of using iterative looping algorithms into an iterative loop process into an array calculations. All methods described here were implemented in the Matlab language (The Mathworks Inc., 2016), with including the Statistics, Curve Fitting, and Signal Analysis Toolboxes. Matlab's Profiler (profile.m) was used to track the memory demand and speed of time to implement calculations. Trials were conducted on multiple desktop systems; for uniformity, analysis shown here data from only used Test-Test runs shown here used in this analysis, that were conducted on one system, in the Windows 10 operating system running on an Intel Core (TM) i7-3720QM processor operating at 2.60GHz with 16GB RAM. Processor clock speed was verified using the Matlab's Profiler tool at run time, and all processing times reported here include are described as both run time (actual observed execution time) and/or as a Total Run Time, which is the sum of CPU time used in for all calculation threads. Example methods are indicated by function name (in italics), and full, commented code scripts for the example functions are provided in the supplementary material. Complete code for this analysis can be obtained directly from the corresponding author. Although these methods were prototyped in Matlab, the examples shown are generally useful as solutions to challenges commonly encountered in micrometeorology. Example data was collected during two various field experiments from 2014- and 2017.5 using an integrated sonic anemometer and infrared gas analyzer (IRGASON) and fine wire thermocouples (FWTs) which was, and was recorded at 10, 20, and 100 Hz using a CR1000 datalogger (Campbell Scientific). The data used in verifying the methods is provided through supplementary materials online (DOI: 10.7267/N9X34VDS).

Vector and array calculations are more efficiently executed than iterative methods; Vectorization vectorization of Matlab code entails removing loops (which are not pre-compiled) and taking advantage of implicit parallel methods in Matlab's pre-compiled library functions (Altman, 2015; Altman, 2015). Other significant improvements were enabled through the Fast Fourier Transform by using convolution of number arrays, rather than iterative operations. In the case of determining ramp geometry in the SR method, Cardano's solution for depressed cubic polynomials (published in 1545) reduces a root finding algorithm from an iterative numerical approximation to an algebraic exact algebraic vector vector calculation. While some of the implementation of these programming methods address unique aspects are particular to the Matlab language, the general mathematical concepts are universal. Although
these methods were prototyped in Matlab, the examples shown are generally useful as solutions to challenges commonly encountered in micrometeorology. By reducing computational overhead, these methods expand the possible uses of SR flux measurements to monitor agricultural water use, to measure from lightweight aerial platforms, and in other specialty applications.

**Example 2.1: Despiking of noisy data using convolution**

Despiking is the removal of erroneous or extreme data points from a time series of sampled values. It is a common procedure when measuring environmental parameters, such as wind speed, temperature, and trace gas concentration especially in challenging conditions or complex environments (Göckede et al., 2004; Starkenburg et al., 2016). The origin of spikes in a time series can be either or physical (sensor malfunction or actual physical non-errors) or electronic in nature. Regardless of the origin, these spikes can be recorded as either abnormally large or small values, or may be marked by some predefined error flag. Spikes become problematic if they are not readily differentiated during automatic data processing (Rebmann et al., 2012). Spikes interfere with normal statistical calculations, and requiring some deliberate and objective method to identify, remove, and interpolate where they exist. For instance, a data logger program may record an error as "9999" or a character string, while Matlab denotes missing values in a numerical array as NaN ("not a number"). Because normally distributed data may contain noise across a wide range of scales, robustness of the despiking algorithm is complicated by the requirement to differentiate between "hard spikes" characteristic of automatic flags (such as 9999) and "soft spikes" which are realistically valued, but exceed some objective limit erroneous measurement. This objective limit for soft spikes is usually defined as appropriate for the signal to noise ratio of any particular data, usually in terms of variance during a stationary defined windowing period. Clearly distinguishing these explicit errors and flagged errors can be achieved by a static objective criteria, by a dynamic statistic, or in a separate pre-processing operation. Previous authors have described a variety of methods including use of autocorrelation (Højstrup, 1993), and statistics within a moving window (Vickers and Mahrt, 1997). A comprehensive review of despiking methods is presented by Starkenburg et al., (2016), with emphasis on the accuracy and statistical robustness of different computation methods.

Despiking is largely a problem of conditional low pass filtering; consequently this procedure can be treated as an application of signal conditioning processing which can be therefore performed efficiently using convolution. Mathematically, convolution can be understood as a multiplicative function that combines a data signal with a filter signal. For a discrete signal, the filter is a weighting array, the size of the moving window, which is multiplied (in the Fourier domain) with data inside the a window. In the time domain, the window can be visualized which it is as moving along the data array as it is multiplied. For As examples, a window-filter with a weight of 2 at the center of the window, and zeros elsewhere, would amplify the data signal by a factor of two. Convolution with a window-filter 10 units-samples wide, each weighted at 0.1, generates a 10 samples running average (smoothed) of the data over 10 samples. The computational efficiency of convolution is a result product of the Fast Fourier.
Transform (FFT), which allocates memory efficiently by a process known as bit switching. A thorough treatment of bit switching can be found in Chapters 12 and 13 of Press (2007). To demonstrate the increased efficiency of the FFT, two programs were used to despike 8.5 hours of 20 Hz sonic temperature data (609,139 samples). A first attempt utilized a sliding window in a for loop, following the objective criteria described by Vickers and Mahrt (1997). An improved second program method (shown in despike.m) used convolution to determine a running mean and standard deviation used in the identification of spikes. After multiple runs with different input criteria, the first program average run time was 27 seconds. Using convolution, the second program average run time was 0.2 seconds, decreasing run time by approximately 99%. While this drastic improvement may potentially overemphasize the slow compile times of for loops in Matlab (compared to other languages), it nonetheless demonstrates the value of the FFT in speeding calculations with time domain signal conditioning signals. Faster processing time and facilitated the abandonment of time saving strategies used in earlier applications of despiking, such as skipping samples or limiting window size, more comprehensive, calibrated, and accurate analysis, and can reduce data loss compared to coarser filtering techniques.

To measure recorded computation time independently of hardware (processor speed and RAM size), identical 10 Hz data was sub-sampled into record lengths from 0.25 to 48 hours, and multiple runs were despiked with each sample set. Raw data was checked for hard error flags which required text to number conversion, but was not otherwise manipulated prior to despiking. Matlab Profiler was used to track the run time for all threads, using the undocumented flag "built-in" to track pre-compiled Matlab functions as well as custom user functions\(^1\). The total run time for all threads was tabulated and averaged across sets of each data length (Figure 1). Despiking in despike.m was accomplished with convolution used to calculate the running mean and running standard deviation arrays, which are used as comparators in identifying spikes (see supplementary materials). By using convolution, despiking was two orders of magnitude faster for all lengths of data. To illustrate the effect of Matlab's built-in parallel processes, Figure 2 shows the ratio of actual run time to Total Run Time, indicating that the convolution method relies on computations conducted in parallel for processing increasingly larger data records. This benefit is direct accrued from the efficiency of the FFT.

With increased computation speed, automatic and accurate despiking can be accomplished, with reduced time cost to determine any necessary calibrate for the procedure. The various methods employed to despike data are variously limited by computational inefficiency (Starkenburg et al., 2016). "Phase space thresholding", originally described by Goring and Nikora (2002) is one such method that Starkenburg noted as being hampered by computational costs, and by a requirement for iterative applications to calibrate despiking parameters. By decreasing the execution time, a similar method was developed that allows rapid and accurate despiking of data, both for the detection of hard and soft spikes. A phase space method allows objective criteria to be calibrated for specific sensor data, and a visual diagnostic phase space diagram that allows for rapid calibration of the despiking criteria (Figure 3). Projecting the signal into a phase space diagram reveals modes related to sensor error, response time, and other factors leading to spikes. Using convolution to determine moving window statistics (such as a moving mean, standard deviation, etc.), objective identification of behaviors characteristic to a particular sensor response. In figure 3, infrared gas analyzer

\(^1\) http://undocumentedmatlab.com/blog/undocumented-profiler-options-part-4, Accessed January 2017
data (in this case, signal strength) collected at 20Hz for 17 days is projected with one minute moving window statistics. Based on this projection, a cut-off in phase space for spike identification can be assigned, and the subsequent percentage of removed data calculated. In this case, the sensor was repeatedly affected by dust from farm operations (Figure 4), yet only 1.5% of the data was required to be removed as spikes due to the precision of the despiking algorithm. This procedure took less than five seconds of computation.

**Figure 1:** The total computation time is the sum of CPU time spent on all calculation threads. Marker is the mean run time for multiple runs, which varied from 30 runs (15min - 4h data) to 10 runs (8, 12, 24 h). 48h calculation is represented by one run only. Error bars represent one standard deviation of all runs.

**Figure 2:** In addition to faster overall run times, calculation of larger data sets remains fast in part due to implicit parallel processing via the Fast Fourier Transform, which can be readily conducted on multiple threads. Parallel processing of noise in the loop method is not apparent.

**Example 2.2:** Structure function calculation

Another computationally-intensive process in SR is the determination of the 2nd, 3rd, and 5th order structure functions. Ramps are an identifiable feature in the measured temperature trace above any natural surface, yet calculating determining the the amplitude of characteristic ramp geometries from high frequency data requires an
efficient, robust, and preferably automated procedure. There are several methods to determine ramp geometry, including visual detection (Shaw and Gao, 1989), low pass filtering (Katul et al., 1996; Paw U et al., 1995), wavelet analysis (Gao and Li, 1993), and structure functions (Spano et al., 1997). Structure functions in particular provide both objective criteria to detect ramps and an efficient method to tabulate ramp geometry statistics of time series data, and use of structure functions has become the predominant method used for SR. The general form for a structure function is:

$$S^n(r) = \frac{1}{N-r} \sum_{i=1}^{i=1,N} \left[ T(i+r) - T(i) \right]^n.$$  

Equation (1)

in which a vector of length N-1 is composed of the differences between sequential (Temperature) samples T(i), separated by lag r. The structure function S^n(r) of order n for a given sample time lag r is obtained by finding differences between each sample i and sample i+r (lagged in time by r samples). The nth order structure function are defined by the nth power in the summation raising the difference vector to the n power, summing the vector and normalizing by N-1. In a turbulent flow field, the sampled fluctuations of scalar time series of signal AT(i) in a turbulent flow can be shown to bear a combination of random fluctuations and coherent structures (Van Atta and Park, 1972). The random (incoherent) part of the signal is produced a product by of isotropic turbulent processes, and over an a-statistically significant large sample this sample should thus has no particular directional sense or orientation (by the isotropic definition). On the other hand, By contrast, coherent structures are by definition generate characteristic anisotropic anisotropesignatures, with periods of gradually change punctuated by period and sharp transitions. These sharp transitions occur during "sweeps and ejections" of parcels enriched or depleted in scalar concentration (heat or water trace gas), evidence of transport from an Eulerian perspective. The total variance is composed of additive random and coherent components, and structure functions can be used to decompose the measured trace time series fluctuations into random and coherent isotropic and anisotropic components and identify the characteristic ramp amplitude and duration of coherent structures (Van Atta, 1977).

Advances in sensor response time and processor speed have revealed an increasingly detailed picture of the coherent ramp structures. In deriving a method to find ramp geometry, Van Atta (1977) calculated structure functions for eight different lags. Two decades later, increased processor power and memory size allowed Snyder et al., (1996) to calculate structure functions on 8 Hz data for lags from 0.25-1.0 seconds, but they were unable to resolve fluxes accurately at some measurement heights and surface roughness conditions. Later it was realized that determining the contributions from "imperfect ramp geometry" would require more thorough examination of ramp durations (Chen et al., 1997a; Paw U et al., 2005) and the convolution method, accomplishes this same calculation was accomplished.
in 7.6 seconds, an ~80% reduction in execution time. The function strfnc.m (provided in Supplementary Materials, S1) also simultaneously time stamps the averaging period, finds the sign of $S^3(r)$ (used to find flux direction), and indexes the maximized value of $S^3(r)/r$, preparing the data for subsequent steps in determining flux. Using 100 Hz FWT data increased the processing time using the convolution method to 38.4 seconds, demonstrating that the loop based method would be too slow to enable the processing of 100 Hz data with large data sets or in real-time applications, and would require long calculation time when using large continuous data records.

For a total of N sample lags, two-dimensional convolution is accomplished by using a filter matrix, which is composed of each column vector of length N+1: \[ [1 -1 0 0 \ldots 0], [1 0 -1 0 \ldots 0], \ldots [1 0 0 \ldots -1] 0 \ldots -1] \]. Each column in the filter represents a matrix representing a time-sample lag increasing distance. When the filter matrix is convolved with time series data, the resulting column matrix is composed of vectors of the resulting matrix are difference vectors, each representing the difference of the element-wise differences $(T(i+r) - T(i))$ as in Eq. 1; these vectors correspond to each sample lag in the at each sequential lag for $r$ (Equation 1) filter. Trials of 10Hz data using Matlab's Profiler showed that calculation efficiency is not accrued directly from convolution, but by changing the order of implementation when multiplying large arrays (for exponentials) and summing. In the looping method, the 2, 3, and 5th exponentiation ($n = 2, 3, 5$) is conducted on the difference vectors for each lag separately. The Exponentiation is implemented accelerated exponentiation in the convolution method via in strfnc.m is possible by using matrix multiplication of large matrices on the convolved matrix, which and is possible faster once the data is reordered due to compact memory allocation of the FFT-2-d convolution. The resulting efficiency (calculation time for a given data size) is not dependent on total data size, but is strongly dependent on the length of the averaging period used to calculate flux (partition the data (Figure 5) (Figure 3). In other words, the choice of averaging period length is the most significant factor in computation time of the maximized structure function used to determine ramp geometry. Computation time increases rapidly for periods shorter than 5 minutes. With the ultimate goal of investigating the shortest robust SR measurement period, the length of averaging time, this proves to be a critical consideration in iterative SR calculations used to developing a rapid SR measurement method.

In most SR studies to determine flux, a lag time is assigned to the structure function calculation, with only a few authors allowing for a procedure to maximize the ratio $S^3(r)/r$ (Shapland et al., 2014). Yet lag time has been
identified as a critical parameter in the linear calibration of ramp geometry to calculate flux (French et al., 2012).

Figure 3: Ten iterations of the structure function calculations using a range of averaging periods.

Because the ideal SR calculation must identify the lag which maximizes the ratio \( S^3(r)/r \), the strfunc.m procedure calculates also be scripted to evaluate structure functions for a continuous range of lags up to some maximum assigned maximum lag - number of lagged samples. Based on repeated trials over a broad range of stability conditions, a short maximum lag (3-5 seconds) may be usually adequate under some atmospheric instability conditions. Following the model of parcel residence time, this is likely a result of in which buoyancy drives-and higher temperature-flux magnitude via leading to rapidly transporting coherent structures shorter ramp duration. Under stable conditions, though, longer lags are required to may be important to detect the true maximum of the ratio \( S^3(r)/r \), indicating that the largest flux contributing time scale contributing to flux increases. To evaluate the sensitivity to the maximum calculated maximum lag, the total run time was structure functions were calculated iteratively ted with varying the averaging periods and maximum tested lag times (Figure 46). For all Regardless of the length of the assigned range of likely maximum lags, the convolution method outpaced was between 4 and 14 times faster than the loop method by a factor of 4-14, with short averaging periods again the largest factor in the difference in total run time between the two methods. Using the 2-d convolution, automated selection of a lag in a continuous time series is feasible.
Figure 4: The performance gains using convolution are more significant for short averaging periods, regardless of maximum lag used in calculating structure functions.

Example Method 2.3: Cardano’s method for depressed cubic polynomials

For the idealized SR method, the calculated structure functions are calculated retained (for each averaging period) at some lag which maximizes the ratio $S^3(r)/r$ - this lag is associated with the theoretical maximum contributing scale of flux. The resulting values are used as coefficients in a cubic polynomial, the root of which is the ramp amplitude ($A$) used to calculate flux:

$$A^3 + \left(10S^2(r) - \frac{S^5(r)}{S^3(r)}\right)A + 10S^3(r) = 0$$

Equation (2)

The magnitude of the real root (of 3 possible roots) is regarded as the corresponding solution for the characteristic ramp amplitude of the scalar trace (Spano et al., 1997). The Matlab root finding algorithm computes eigenvalues of a companion matrix to approximate the solution to a $n^{th}$ order polynomial, regarding the input function as a vector with $n+1$ elements (roots.m documentation). Consequently, this function cannot be executed directly on an array. On the other hand, the algebraic solution method can be applied to vectors. An appropriate method for this type of cubic polynomial was proposed found by Gerolamo Cardano in the 1545 Ars Magna. Cardano’s solution for “depressed” cubics (with no squared term) on the other hand, can be applied to vectors. Cardano’s solution is found by substituting $A$ with $(m^{1/3} + n^{1/3})$ into the abbreviated equation $A^3 + pA + q = 0$.

Expanding terms and using the quadratic equation yields an exact solution:

$$A = \left(-\frac{q}{2} + \sqrt{\left(\frac{q}{2}\right)^2 + \left(\frac{p}{3}\right)^3}\right)^{1/3} + \left(-\frac{q}{2} - \sqrt{\left(\frac{q}{2}\right)^2 + \left(\frac{p}{3}\right)^3}\right)^{1/3}$$

Equation (3)

where $p$ and $q$ are the coefficients of the depressed cubic and derived from the structure functions (Edwards and Beaver, 2015). The function cardanos.m was adapted from a function by Bruno Luong, in a reduced form for the real valued cases used to implement the SR method. The function output was verified against the Matlab function roots.m for polynomials with both positive and negative real valued inputs (imaginary inputs are applicable to ramp parameters). Solution for the real roots in this manner expedites rapid SR flux calculation of ramp amplitude, and facilitates the determination of flux direction. The decreased time of implementation is trivial in this example; rather, algebraic root finding method on arrays dramatically simplifies and speeds iterative application of the SR method by operating directly on arrays.

Solving for the roots of this function yields a single, predominant ramp amplitude from a given temperature trace (with units of °C or K). In addition to ramp amplitude, the time scale or ramp duration must also be determined. (Van Atta, 1977) suggested that ramp time $\tau$ should be related linearly to amplitude $A$, and proposed:

---

In practice, determination of ramp time $\tau$ from $A$ using this equation requires an empirical calibration; this calibration has been shown to be related to surface conditions and instrumentation (Chen et al., 1997b; Shapland et al., 2014). Ongoing work using replicate measurements at multiple heights (Castellvi, 2004) and frequency response calibration (Shapland et al., 2014; Suvočarev et al., 2014) have begun to resolve the causes of variability in this parameter. In this study, it was found that the ratio in equation 4 remains essentially constant for a given surface roughness condition, allowing determination of $\tau$ algebraically. Automated computation of equation 2 using the exact solution facilitates rapid evaluation of the ramp geometry, and determining flux magnitude from ramp geometry is a relatively simple matter of linear scaling when calibrating to a control measure such as eddy covariance.

3 Conclusions

As with other methods for measuring flux from surface flow parameters such as flux and turbulent, analytic solutions do not always translate easily into straightforward numerical computation, especially when working with large data records or when calculating in real-time of high frequency data. In applied research, despite advances in data storage, memory size, and processor speed, the basic custom programming methods used algorithms for analysis are often developed by individual researchers, requiring special who often do not have training in programming, significant time investment, or the motivation to develop sophisticated programming methods. Techniques that fully utilize available memory and processing power. Efforts to standardize the eddy covariance method (Aubinet et al., 2012; Baldocchi, 2014) and data quality control (Allen et al., 2011; Foken et al., 2012) have not yet been similarly applied to the SR method, although substantial work has been made to validate calibration and unify SR methods and field methods (Castellvi, 2012; Chen et al., 1997b; French et al., 2012; Suvočarev et al., 2014). By appropriating methods common to other disciplines such as signal processing, and by sharing open source tools using online forums such as stackexchange.com, more sophisticated approaches can be implemented more broadly. One goal of these open source efforts should be to reduce the computational overhead of calculating flux enables, so as to facilitate the broadest implementation and robust verification of the SR method in applied contexts. Rapid algorithms allow for automated assignment of lag time, rather than fixed assignment, and allow flux determinations while varying the length of flux averaging periods. These procedures allow for comprehensive analysis of both the physical time scales of surfaces flux, and the sensor response and uncertainty associated with the SR derived flux. Calibration of despiking criteria can be implemented quickly at low computational cost. In summary, efficient methods for computing SR flux allow implementation in novel deployments such as low cost, continuous
monitoring, and on moving platforms. Future work remains to transfer efficient methods from the Matlab development platform to open source implementations, and enable hardware to perform these techniques directly for real-time applications. Reducing the cost and power requirement of the required data loggers, computers, and telemetry will facilitate the extensive deployment of SR sensors to aid in describing the heterogeneity of flux across the landscape.

4 Data Availability

All data used in this analysis and scripts implementing the algorithms described above are available online at http://hdl.handle.net/1957/60599. This supplementary materials is also listed with DOI: 10.7267/N9X34VDS. Abbreviated scripts for the three example methods may be found in the supplemental materials. Requests for phase-space despiking methods can be directed to the corresponding author.
