

**Author response to anonymous referee #1 on “An intercomparison of HO<sub>2</sub> measurements by Fluorescence Assay by Gas Expansion and Cavity Ring–Down Spectroscopy within HIRAC (Highly Instrumented Reactor for Atmospheric Chemistry)” by L. Onel et al.**

Note: The changes in the manuscript addressing the comments of the referee #1 are highlighted in yellow below. Question 6 was answered before Q4 to follow the order of changes in the text as the answers to Q6 and Q4 are inter-correlated.

**Specific comments**

*Q1: In the abstract, you give the gradient (with a small error bar) of a correlation plot between FAGE and cw-CRDS measurements for both pressures. This gradient depends on the absorption cross sections used for converting the cw-CRDS measurements into absolute concentrations. Further down in the abstract, you precise that you find 2 different absorption cross sections in rather good agreement using two different methods. The reader can get confused about this, and maybe you should precise that the gradient given in the abstract is the average of both values (at least this is what I guess you did). The error bar should also be larger in this case.*

The abstract has been changed according to the suggestion of the referee:

“At 1000 mbar total pressure the correlation plot of [HO<sub>2</sub>]<sub>FAGE</sub> versus [HO<sub>2</sub>]<sub>CRDS</sub> gave an average gradient of  $0.84 \pm 0.08$  for HO<sub>2</sub> concentrations in the range  $\sim 4\text{--}100 \times 10^9$  molecule cm<sup>-3</sup> while at 150 mbar total pressure the corresponding gradient was  $0.90 \pm 0.12$  on average for HO<sub>2</sub> concentrations in the range  $\sim 6\text{--}750 \times 10^8$  molecule cm<sup>-3</sup>.”

*Q2: Page 5, line 17: the sentence “CRDS was chosen for validation of FAGE because it requires no calibration” seems a bit inappropriate to me because as long as the absorption cross section at a given pressure is not well known (which is difficult for radicals), CRDS is not absolute. I could conceive this idea if you do experiments at one given pressure in different chemical environments, and then you use CRDS to validate FAGE against possible interferences, but I think it might be too simplified to say for the moment that you can use CRDS to validate FAGE.*

The line on page 5 has been rephrased:

“The CRDS technique was chosen to confirm the HO<sub>2</sub> measurements by the FAGE method as CRDS is a direct absorption method that does not require the chemical conversion of HO<sub>2</sub> to another species. Reported here are the first CRDS measurements of HO<sub>2</sub> carried out in an atmospheric simulation chamber.”

Q3: Page 12: Did you check if the absorption of the product CH<sub>2</sub>O does contribute to the background? Absorption cross sections for CH<sub>3</sub>OH and CH<sub>2</sub>O are in the same range (Ruth et al., Z Phys Chem 229 (10-12), 1609 (2015)), so I guess that even if yes it would not change your conclusions, as it only counteracts on the decreased background due to CH<sub>3</sub>OH. However, a small discussion on the possible absorption of CH<sub>2</sub>O could be given.

Formaldehyde has a small contribution to the change in the background absorption during the scans shown in Figure 3, page 12. The absorption cross section of CH<sub>2</sub>O at the wavelength of interest, 1506.43 nm,  $\sigma_{\text{CH}_2\text{O}}$ , has been estimated at the two HIRAC operating pressures (150 mbar and 1000 mbar) by measuring the ring-down time at 1506.43 nm before and after delivering CH<sub>2</sub>O in a few known concentrations, determined by using the chamber *in situ* FTIR system. At both pressures  $\sigma_{\text{CH}_2\text{O}}(1506.43 \text{ nm}) \sim 3 \times 10^{-23} \text{ cm}^2 \text{ molecule}^{-1}$ . A few times higher value is shown in Figure 1 reported by Ruth et al. (2015), i.e. cross sections between  $\sim 0.5\text{--}1.5 \times 10^{-22} \text{ cm}^2 \text{ molecule}^{-1}$  at around 1506.43 nm at 2 mbar of pure CH<sub>2</sub>O, which may be explained by a reduced pressure broadening.

The cross sections of CH<sub>3</sub>OH at 1506.43 nm at the two operating pressures are:  $\sigma_{\text{CH}_3\text{OH}, 150 \text{ mbar}} = (9.95 \pm 0.42) \times 10^{-23} \text{ cm}^2 \text{ molecule}^{-1}$  and  $\sigma_{\text{CH}_3\text{OH}, 1000 \text{ mbar}} = (8.11 \pm 0.05) \times 10^{-23} \text{ cm}^2 \text{ molecule}^{-1}$  (supplementary information). Therefore,  $\sigma_{\text{CH}_2\text{O}}$  was about 3 times lower than  $\sigma_{\text{CH}_3\text{OH}}$  at both 150 mbar and 1000 mbar. In the HIRAC experiments, CH<sub>2</sub>O is formed by the CH<sub>3</sub>OH + Cl reaction in the presence of O<sub>2</sub> (in a stoichiometric ratio CH<sub>2</sub>O:CH<sub>3</sub>OH = 1:1), and can react further with Cl. However, during the several minutes required to obtain the laser scans shown in Figure 3, the CH<sub>2</sub>O + Cl reaction was negligible and, hence the [CH<sub>2</sub>O] produced was approximately equal to the decrease in [CH<sub>3</sub>OH]. Therefore, the decrease in background absorption due to the CH<sub>3</sub>OH consumption is  $\sim 30\%$  counteracted by the formation of CH<sub>2</sub>O. In light of this effect, the first paragraph on page 12 has been changed to:

“During the measurements, the background absorption decreased mainly due to the removal of CH<sub>3</sub>OH by the CH<sub>3</sub>OH + Cl reaction (Reaction (R17)). [CH<sub>3</sub>OH] decreased by  $\sim 15\%$  during the scan at 150 mbar and  $\sim 10\%$  during the scan at 1000 mbar, as determined using FTIR measurements (supplementary information), to form CH<sub>2</sub>O through Reaction (R17) followed by (R18). Section S7 in the supplementary information shows that  $\sigma_{\text{CH}_3\text{OH}}$  is  $\sim 3$  times higher than  $\sigma_{\text{CH}_2\text{O}}$  at both pressures, hence  $\sim 30\%$  of the decrease in the absorption background due to the CH<sub>3</sub>OH consumption was counteracted by the formation of CH<sub>2</sub>O. The spectrum was measured from larger to smaller wavelengths (right to left), hence the decrease in background absorption with time (decreasing  $\lambda$ ) during a scan.”

A paragraph has also been added at the end of Section S7 in the supplementary information:

“In addition, a few measurements of the decrease in the ring-down time when CH<sub>2</sub>O was delivered in known concentrations to the chamber have been performed to estimate that the absorption cross section

of CH<sub>2</sub>O at 1506.43 nm is  $\sim 3 \times 10^{-23}$  cm<sup>2</sup> molecule<sup>-1</sup> on average at both 150 mbar and 1000 mbar. This estimated  $\sigma_{\text{CH}_2\text{O}}$  is a few times lower than the value reported by Ruth et al. (2015) using 2 mbar of pure CH<sub>2</sub>O, and can be rationalised by the air-broadening in the present measurements.”

*Q6: However, I would expect that the wall loss constant is a function of the distance to the wall, i.e. close to zero in the center and very high close to the walls. So if for FAGE measurements equation 10 might be right, a uniform  $k_{\text{loss}}$  over the entire absorption path might not be applicable for CRDS measurements. Can you comment on that?*

The investigations into any [HO<sub>2</sub>] gradient across the radius of HIRAC found an almost constant [HO<sub>2</sub>] at both operating pressures (Sect. 2.3.3), as expected as circulation fans were used to homogenize the gas mixture in the chamber. As the HIRAC diameter represented 86% of the cavity length, the approximation of a uniform  $k_{\text{loss}}$  has been employed in the analysis of the HO<sub>2</sub> temporal decays measured by the CRDS system.

A paragraph has been added in Sect. 3.3.1, above Figure 5, to clarify this point:

“The obtained  $\sigma_{\text{HO}_2}$  is in good agreement with  $\sigma_{\text{HO}_2} = (1.25 \pm 0.19) \times 10^{-19}$  cm<sup>2</sup> molecule<sup>-1</sup> generated by the analysis presented in Section 3.2. The wall-loss rate coefficient,  $k_{\text{loss}}(\text{CRDS}) = (0.11 \pm 0.01)$  s<sup>-1</sup>, is slightly higher than  $k_{\text{loss}}(\text{FAGE}) = (0.09 \pm 0.02)$  s<sup>-1</sup>, determined by fitting the kinetic decays to calibrate the FAGE instrument. This result was expected as the FAGE instrument was measuring [HO<sub>2</sub>] in the gas mixture sampled from one point at  $\sim 230$  mm from the HIRAC wall, while CRDS measured across the total width of the chamber (1200 mm) and the two 100 mm long system of flanges coupling the cavity mirrors to the chamber (Fig. 2). The investigations into the [HO<sub>2</sub>] gradient across the HIRAC diameter (86% of the distance between the two cavity mirrors,  $L = 1400$  mm) found a practically constant [HO<sub>2</sub>] (Sect.2.3.3) due to the reactive mixture homogenized by the circulation fans. As the length of the systems of flanges coupling the mirrors, where the reactive mixture might not be homogenized, represented only 14% of  $L$ ,  $k_{\text{loss}}$  was considered uniform over the entire cavity length.”

*Q4: Page 14, line 7: do you use  $l=1,4$  m in equation 9? Are you sure that the HO<sub>2</sub> concentration is homogeneous from the center of the chamber down to the last cm in front of the mirrors? You do not protect your mirrors with a small flow of clean air? I would suspect a strong decrease of HO<sub>2</sub> concentration over (at least) the last 10 cm before the mirrors due to many walls surrounding this area (looking at Figure 2). This of course makes only 20 cm out of a total of 140cm, but still, it might change the conclusions from the observed decay.*

Equation 9 considers that HO<sub>2</sub> is present across the entire cavity length,  $L = 1.4$  m.

The FAGE measurements of HO<sub>2</sub> across the HIRAC width described in Sect. 2.3.3 in the main manuscript showed that [HO<sub>2</sub>] is almost homogeneous across the chamber diameter. The mirrors were not protected with a flow of air. Since the mirrors are in a "recess", we can expect the [HO<sub>2</sub>] to be smaller in their proximity. Future experiments using a flow of clean air in front of the mirrors are planned to test the sensitivity of the results to a virtual zero [HO<sub>2</sub>] in front of the mirrors. In the 'worst case scenario' with the present system (no purge flow in front of the mirrors) [HO<sub>2</sub>] = 0 over a distance of 10 cm in front of the mirrors and, then the absorption coefficient,  $\alpha_{\text{HO}_2}$ , will be higher by a factor  $R = L/L_{\text{HO}_2} = 1.4/1.2 = 1.17$ , where  $L$  is the distance between the two cavity mirrors (1.4 m) and  $L_{\text{HO}_2}$  is the chamber diameter, where HO<sub>2</sub> is present (1.2 m).

A paragraph has been added after Figure 5:

Equation (9) employs the approximation that [HO<sub>2</sub>] is constant along the entire length of the cavity,  $L$ . Future experiments using a flow of clean air in front of the both cavity mirrors are planned to protect them from (potential) contamination due to the reactive mixture and to test if the results of the analysis of the HO<sub>2</sub> temporal decays remain unchanged by a virtual zero concentration of HO<sub>2</sub> in front of the mirrors. Analysis was performed considering the worse case scenario that no HO<sub>2</sub> radicals were present over the two 100 mm distances between the cavity mirrors and the main HIRAC chamber, i.e. [HO<sub>2</sub>] = 0 over 14% of  $L$ . This analysis found the same wall-loss rate coefficient on average,  $k_{\text{loss}} = (0.11 \pm 0.01) \text{ s}^{-1}$ , as the average value obtained assuming that [HO<sub>2</sub>] is constant across the entirety of  $L$ . The extracted  $\sigma_{\text{HO}_2}$ ,  $(1.18 \pm 0.22) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  on average, has overlapping overall errors (at the  $1\sigma$  level) with that found by the analysis where [HO<sub>2</sub>] was considered homogeneous along the entire  $L$ ,  $(1.02 \pm 0.18) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  (further details in Sect. S9.2 in supplementary information).

A paragraph and a table (Table S5) have also been added at the end of the Sect. S9.2 in the supplementary information:

“As the cavity mirrors are mounted 100 mm from the chamber internal wall, [HO<sub>2</sub>] is expected to be lower along the 100 mm distance before each mirror compared to [HO<sub>2</sub>]<sub>HIRAC</sub>. Investigations have been carried out to test the sensitivity of the results shown in Table S4 to the approximation that [HO<sub>2</sub>] is homogeneous across the entire cavity length (the distance between the mirrors),  $L = 1400$  mm. The absorption coefficient has been re-computed by considering that HO<sub>2</sub> is absent in the systems of flanges connecting the mirrors to the chamber (14% of  $L$ ). In this worst case scenario, the absorption coefficient is higher by a factor equal to the ratio between  $L$  and the HIRAC diameter, where HO<sub>2</sub> is present,  $L_{\text{HO}_2}$  (1200 mm):

$$\alpha_{\text{HO}_2} = \frac{L/L_{\text{HO}_2}}{c} \left( \frac{1}{\tau} - \frac{1}{\tau_0} \right) = \frac{1.17}{c} \left( \frac{1}{\tau} - \frac{1}{\tau_0} \right), \quad (\text{S6})$$

The fit of Eq. (S5) to the experimental temporal decays of  $\alpha_{\text{HO}_2}$  computed using Eq. (S6) yielded the results shown in Table S5. The averaged values of the parameters are:  $\sigma_{\text{HO}_2} = (1.18 \pm 0.22) \text{ cm}^2 \text{ molecule}^{-1}$  and  $k_{\text{loss}} = (0.11 \pm 0.01) \text{ s}^{-1}$ . It can be concluded that the use of the factor of 1.17 results in a change in  $\sigma_{\text{HO}_2}$  within its overall  $1\sigma$  error and does not change  $k_{\text{loss}}$ .”

*Q5: Page 14, determination of sigma\_HO2: You consider the wall loss for CRDS measurements to be the same for FAGE and for CRDS measurements.*

We determined the value of  $k_{\text{loss}}$  by treating it as a floating parameter in the fits to the kinetic decays. At 150 mbar  $k_{\text{loss}}$  obtained for the CRDS measurements is slightly higher than the one found by the analysis of the FAGE data, as expected as FAGE sampled from a point close to the middle of HIRAC, while CRDS measured across the chamber diameter:  $k_{\text{loss}}(\text{CRDS}) = (0.11 \pm 0.01) \text{ s}^{-1}$  (Section 3.3.1, page 14) and  $k_{\text{loss}}(\text{FAGE}) = (0.09 \pm 0.02) \text{ s}^{-1}$  (Section 2.3.2, page 9). There is an almost constant  $[\text{HO}_2]$  across the HIRAC radius (using FAGE measurements of  $\text{HO}_2$ ; Section 2.3.3) showing/indicating that the circulating fans have homogenized the concentration within the chamber. The small difference (20%) between  $k_{\text{loss}}(\text{CRDS})$  and  $k_{\text{loss}}(\text{FAGE})$  is due to the two cavity mirrors mounted on the outside of HIRAC, 100 mm apart from the chamber, where the gas mixture might not be homogenized. However, 200 mm represents only 14% from the entire cavity length (1400 mm), explaining why  $k_{\text{loss}}(\text{CRDS})$  and  $k_{\text{loss}}(\text{FAGE})$  are relatively similar to each other (overlapping error limit at  $1\sigma$  level).

The precision in the CRDS measurement was poorer at 1000 mbar than at 150 mbar. Therefore, at 1000 mbar the FAGE signal decays recorded simultaneously with the  $\alpha_{\text{HO}_2}$  temporal decays were scaled to overlap  $\alpha_{\text{HO}_2}$  vs. time and then analysed to obtain  $\sigma_{\text{HO}_2}$  (Sect. 3.3.2, page 15). This assumption has been made as the scaled FAGE measurements were in a very good agreement with the CRDS measurements (Figure 6 in the main manuscript), suggesting that a possible small difference between  $k_{\text{loss}}(\text{CRDS})$  and  $k_{\text{loss}}(\text{FAGE})$ , similar to the difference found at 150 mbar, is ‘unobservable’. In addition, even though the analysis of the CRDS data resulted in significantly higher statistical errors in  $\sigma_{\text{HO}_2}$ , the average value agrees very well with the average  $\sigma_{\text{HO}_2}$  obtained by the analysis of the scaled fluorescence signal:  $\sigma_{\text{HO}_2}(\text{CRDS}) = (3.68 \pm 0.69) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  and  $\sigma_{\text{HO}_2}(\text{FAGE}) = (3.87 \pm 0.11) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$ . The value of  $k_{\text{loss}}(\text{CRDS})$ ,  $(0.076 \pm 0.028) \text{ s}^{-1}$  is higher but has overlapping error limits with  $k_{\text{loss}}(\text{FAGE}) = (0.045 \pm 0.004) \text{ s}^{-1}$ .

In light of these comments, section 3.3.2 of the main manuscript has been changed as follows:

“...Therefore, the statistical uncertainties in the kinetic analysis of the  $\alpha_{\text{HO}_2}$  temporal decays were relatively high at 1000 mbar, having values of 19% in  $\sigma_{\text{HO}_2}$  and 37% in  $k_{\text{loss}}$  at the  $1\sigma$  level on average. By comparison, the precision of the kinetic method at  $1\sigma$  level at 150 mbar was 3% in  $\sigma_{\text{HO}_2, 150 \text{ mbar}}$  and 10% in  $k_{\text{loss}, 150 \text{ mbar}}$ . In order to reduce the CRDS statistical uncertainties at 1000 mbar, the FAGE signal decays monitored at the same time with the  $\alpha_{\text{HO}_2}$  decays were used to determine  $\sigma_{\text{HO}_2, 1000 \text{ mbar}}$ . In this approach the fluorescence signal decays were scaled to overlap  $\alpha_{\text{HO}_2}$  vs. time by multiplying the FAGE signal by  $f = \frac{(\bar{\alpha}_{\text{HO}_2})_0}{(\bar{S}_{\text{HO}_2})_0}$ , where  $(\bar{\alpha}_{\text{HO}_2})_0$  and  $(\bar{S}_{\text{HO}_2})_0$  are the mean absorption coefficient and the mean FAGE signal before the UV lamps are turned off. Equation (10), where  $k_{\text{self-r.}}$  was fixed to  $2.85 \times 10^{-12} \text{ cm}^{-3} \text{ molecule}^{-1} \text{ s}^{-1}$  (Atkinson et al., 2004), was fitted to the scaled signal decays (Fig. 6 shows an example) to obtain an average  $\sigma_{\text{HO}_2(\text{FAGE})} = (3.87 \pm 0.74) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  (further details in supplementary information), where the error limits are overall errors (19%) quoted at the  $1\sigma$  level. The value of  $\sigma_{\text{HO}_2(\text{FAGE})}$  agrees very well with the average absorption cross section obtained by fitting Eq. (10) to the temporal decays recorded by the CRDS system,  $\sigma_{\text{HO}_2(\text{CRDS})} = (3.68 \pm 0.99) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  (Sect. 9.3 in supplementary information), where the overall  $1\sigma$  uncertainty is 27%. Both values are in good agreement with  $\sigma_{\text{HO}_2} = (3.44 \pm 0.37) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  computed by the model described in Section 3.2, which considered the contribution of the air-broadened  $\text{HO}_2$  absorption lines (Thiebaud et al., 2007) to the overall cross section at 1506.43 nm. As the precision in  $\sigma_{\text{HO}_2(\text{FAGE})}$  (3%) is much higher than the precision in  $\sigma_{\text{HO}_2(\text{CRDS})}$  (19%),  $\sigma_{\text{HO}_2(\text{FAGE})}$  was used in the intercomparison of the CRDS and FAGE measurements (Sect. 3.5.2).”

A new paragraph also been added at the end of the section S9.3 in the supplementary information:

“The scaled FAGE signal decays were employed to determine  $\sigma_{\text{HO}_2}$  as the scaled  $S_{\text{HO}_2}$  decays overlapped very well with the  $\alpha_{\text{HO}_2}(1000 \text{ mbar})$  vs. time measurements (Figure 6 in the main manuscript shows an example). In addition, the analysis of  $\alpha_{\text{HO}_2}(1000 \text{ mbar})$  vs. time using Eq. (S5) provided an average  $\sigma_{\text{HO}_2(\text{CRDS})} = (3.68 \pm 0.69) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  (Table S6) in very good agreement with  $\sigma_{\text{HO}_2(\text{FAGE})}$ . The average rate coefficient of the wall-loss was  $k_{\text{loss}}(\text{CRDS}) = (0.076 \pm 0.028) \text{ s}^{-1}$  and, hence  $k_{\text{loss}}(\text{CRDS})$  and  $k_{\text{loss}}(\text{FAGE})$  have overlapping error limits. The standard errors in the fit to the CRDS data were much higher than the standard errors in the fit to the scaled FAGE data: 19% associated with  $\sigma_{\text{HO}_2(\text{CRDS})}$ , compared to the only 3% fit precision in  $\sigma_{\text{HO}_2(\text{FAGE})}$  and 37% associated with  $k_{\text{loss}}(\text{CRDS})$  compared to the ~ 4 times lower fit precision in  $k_{\text{loss}}(\text{FAGE})$  (10%).

**Table S6.**  $\sigma_{\text{HO}_2}(1506.43 \text{ nm})$  and the wall-loss rate coefficient within HIRAC,  $k_{\text{loss}}$ , at 1000 mbar obtained by fitting Eq. (S5) to: (i) the temporal decays obtained by multiplying the FAGE signal,  $(S_{\text{HO}_2})_t$ , with  $f = \frac{(\bar{\alpha}_{\text{HO}_2})_0}{(\bar{S}_{\text{HO}_2})_0}$ , where  $(\bar{\alpha}_{\text{HO}_2})_0$  and  $(\bar{S}_{\text{HO}_2})_0$  are the average absorption coefficient and the mean FAGE signal before the UV lamps are extinguished, and (ii)  $\alpha_{\text{HO}_2}(150 \text{ mbar})$  vs. time.

$10^{20} \times \sigma_{\text{HO}_2, \text{FAGE}}^a$ / $\text{cm}^2 \text{ molecule}^{-1}$	$k_{\text{loss, FAGE}}^a / \text{s}^{-1}$	$10^{20} \times \sigma_{\text{HO}_2, \text{CRDS}}^a$ / $\text{cm}^2 \text{ molecule}^{-1}$	$k_{\text{loss, CRDS}}^a / \text{s}^{-1}$
$3.65 \pm 0.04^b$	$0.046 \pm 0.004$	$3.89 \pm 0.52^b$	$0.08 \pm 0.01$
$3.54 \pm 0.06^b$	$0.029 \pm 0.008$	$3.47 \pm 0.47^b$	$0.07 \pm 0.02$
$3.29 \pm 0.05^b$	$0.028 \pm 0.002$	$4.30 \pm 0.26^b$	$0.07 \pm 0.02$
$4.08 \pm 0.06^b$	$0.034 \pm 0.005$	$3.27 \pm 0.68^b$	$0.08 \pm 0.03$

<sup>a</sup> uncertainties quoted to  $1\sigma$

<sup>b</sup>  $[\text{HO}_2]_0 \sim 1 \times 10^{10} \text{ molecule cm}^{-3}$  (obtained by using:  $[\text{HO}_2]_0 = (\alpha_{\text{HO}_2})_0 / \sigma_{\text{HO}_2}$ )

<sup>c</sup>  $[\text{HO}_2]_0 \sim 6 \times 10^{10} \text{ molecule cm}^{-3}$  (computed by using:  $[\text{HO}_2]_0 = (\alpha_{\text{HO}_2})_0 / \sigma_{\text{HO}_2}$ )”

**Author’s note:** As circulation fans were used during all the experiments, the “movement” of  $\text{HO}_2$  within the chamber is only in part molecular diffusion, the rest is convection. Therefore, the below sentence was removed from the main text in Sect. 2.3.2 before Figure 1:

“Note that the parameter  $k_{\text{loss}}$  is dependent on the chamber conditions during the experiment and decreases with increasing pressure as expected for diffusive loss being the rate determining step in the wall-loss process; a value of  $k_{\text{loss}} = (0.04 \pm 0.01) \text{ s}^{-1}$ , has been obtained by the kinetic analysis of the FAGE signal decays measured at 1000 mbar in HIRAC in this work.”

*Q7. Looking at the absorption cross sections, I see that your measured value at 150 mbar ( $1.02\text{e-}19$ ) is around 20% below the calculated one ( $1.25\text{e-}19$ ), while at 1000 mbar the measured value ( $3.87\text{e-}20$ ) is around 10% above the calculated one ( $3.44\text{e-}20$ ). Why you say broad agreement for the 1000mbar and good agreement for the 150mbar, I would say the other way around, but maybe my English is not perfect...*

The reviewer is right. Now ‘broad’ and ‘good’ are the other way round.

Q8. Even though the error bars are overlapping for both pressures, I'm still wondering why the measured value is above at 1000 mbar and below at 150 mbar, compared to the calculated one. Pressure broadening has a very strong impact on the 1000 mbar value, so comparing it with the measured one I conclude that the broadening coefficients have been slightly overestimated in the calculations. So fine-tuning the broadening coefficient to the measured  $\sigma_{\text{HO}_2}$  at 1000 mbar, and then re-calculating the value at 150 mbar, should lead to a ~10% higher value at 150 mbar. Now the error bars start to not agreeing anymore. Could the diffusion be linked to this?

A value of  $(3.44 \pm 0.37) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  was computed for  $\sigma_{\text{HO}_2}(1506.43 \text{ nm})$  at 1000 mbar assuming that the air-broadening coefficients for the absorption line centred at 1506.43 nm and the nearby lines are all the same and equal to the value reported by Ibrahim et al., (2007). However, no study has been performed to test if the broadening coefficients are (nearly) identical for all the absorption lines overlapping at 1000 mbar. Therefore, tuning the value for the “global” broadening coefficient to best fit  $\sigma_{\text{HO}_2}(1000 \text{ mbar})$  obtained by the analysis of the HO<sub>2</sub> kinetic decays ( $(3.87 \pm 0.74) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$ ) is not necessarily correct. For example, if the values of the broadening coefficients,  $\gamma_i$ , for the spectral lines in the vicinity of 1506.43 nm are higher than the broadening coefficient for the line centred at 1506.43 nm,  $\gamma(1506.43 \text{ nm})$ , then a slightly higher  $\sigma_{\text{HO}_2}(1000 \text{ mbar})$  would be obtained than  $\sigma_{\text{HO}_2}(1000 \text{ mbar})$  calculated here assuming  $\gamma_i = \gamma(1506.43 \text{ nm})$ . The value of  $\sigma_{\text{HO}_2}(1000 \text{ mbar})$  obtained using  $\gamma_i = \gamma(1506.43 \text{ nm})$  is 10% smaller than  $\sigma_{\text{HO}_2}(1000 \text{ mbar})$  determined by the kinetic method, suggesting that indeed  $\gamma_i > \gamma(1506.43 \text{ nm})$ . However, if  $\gamma_i > \gamma(1506.43 \text{ nm})$  a 10% higher  $\sigma_{\text{HO}_2}$  at 1000 mbar does not extrapolate into 10% higher  $\sigma_{\text{HO}_2}$  at 150 mbar, as the overlapping of the spectral lines at 150 mbar is less significant than the line overlapping at 1000 mbar. In addition,  $\sigma_{\text{HO}_2}(150 \text{ mbar}) = (1.25 \pm 0.19) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  computed by using the reported spectral data agrees very well with the value found by Tang et al. (2010),  $\sigma_{\text{HO}_2, 150 \text{ mbar}} = (1.29 \pm 0.23) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$ . We have therefore chosen not to make this (suggested) correction but simply make sure that we state the assumptions inherent in our modelling of the spectra.

Q9. (A) I have plotted your data from tables S4 and S5, i.e.  $k_{\text{loss}}$  as a function of the absorption cross section. For both pressures there is a tendency of increased loss rate with increased  $\sigma$  (same trend is visible for the FAGE calibration factors).

(B) It would be interesting to see if there is also a correlation with the initial radical concentration. I see that you have varied the initial Cl<sub>2</sub> concentration by a factor of 3 to 4, but unfortunately these values are not given in the tables. Can you comment on that?

Answer to Q 9(A):

Analysis has been performed to investigate whether the weak correlation between  $k_{\text{loss}}$  and  $\sigma_{\text{HO}_2}$  had an effect on the fitting of the results using Eq. (10) (corresponding to Eq. (S5) in Sect. 9.2 in the supplementary information). The parameter  $\sigma_{\text{HO}_2, 150 \text{ mbar}}$  was fixed to the value obtained by using the reported spectral data,  $1.25 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  while  $k_{\text{loss}}$  was floated. The best fit returned a  $k_{\text{loss}}$  value

ca. 30% higher than that obtained by floating both  $k_{\text{loss}}$  and  $\sigma_{\text{HO}_2}$ . However, the goodness of the fit was poorer, as shown by the values of the reduced chi-squared: (i)  $0.9 \times 10^{-21}$  when both  $k_{\text{loss}}$  and  $\sigma_{\text{HO}_2}$  were floated and (ii)  $1.5 \times 10^{-20}$  when  $\sigma_{\text{HO}_2}$  was fixed to  $1.25 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  and only  $k_{\text{loss}}$  floated.

In addition, the analysis of the FAGE signal decays at 1000 mbar generated a FAGE calibration factor ( $C_{\text{HO}_2} = (2.4 \pm 0.5) \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$ ) in very good agreement with the calibration factor at atmospheric pressure obtained by the conventional method of calibration using the flow tube ( $C_{\text{HO}_2} = (2.6 \pm 0.4) \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$ ). This very good level of agreement shows that the kinetic analysis of the FAGE and CRDS data, respectively, provides a reliable method of determination of  $C_{\text{HO}_2}$  and  $\sigma_{\text{HO}_2}$ . Therefore, we think that no modification of the text is necessary.

*Answer to Q 9(B) (It would be interesting to see if there is also a correlation with the initial radical concentration. I see that you have varied the initial Cl2 concentration by a factor of 3 to 4, but unfortunately these values are not given in the tables. Can you comment on that?):*

The initial values for  $[\text{HO}_2]$  are given in the text below the tables S4 – S6, which show  $\sigma_{\text{HO}_2}$  and  $k_{\text{loss}}$  obtained by the analysis of the absorption coefficient temporal decays at the two pressures. At 150 mbar all the values of  $\sigma_{\text{HO}_2}$  agree within ~ 3% even if the initial concentration of  $\text{HO}_2$  was changed by a factor of two (Table S4). At 1000 mbar an increase in  $[\text{HO}_2]_0$  by a factor of ~2 corresponds to ~ 20% increase in  $\sigma_{\text{HO}_2}$ (FAGE) and practically same  $\sigma_{\text{HO}_2}$ (CRDS) (agreement within ~ 3%). Therefore, it can be concluded that the analysis results are independent of  $[\text{HO}_2]_0$ .

The main text above Fig. 5 has been changed to:

“Eq. (10) was fitted to eight temporal traces (Fig. 5 shows an example) where the  $(\alpha_{\text{HO}_2})_0$  was varied by a factor of two to obtain an average  $\sigma_{\text{HO}_2} = (1.02 \pm 0.18) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  (Table S4 in the supplementary information), where the error is a combination of systematic and statistical uncertainties at the  $1\sigma$  level. The statistical error was only 3% showing that the analysis results are independent of  $[\text{HO}_2]_0$ .”

### Technical corrections

*Page 3, line 26: you describe general CRDS, but the switching off the laser beam above threshold is specific to cw-CRDS. Maybe this detail is not needed in the introduction; it might be confusing to the reader not familiar with CRDS.*

Line 26 on page 3 has been changed as suggested by the referee:

“If the laser frequency matches one of the cavity resonance frequencies, optical power within the resonator quickly builds up, and a fraction of the circulating power leaks out through one mirror. A photodetector located at the back of this mirror measures the exponential decay in the light intensity (‘ring-down’) with a time constant that is a measure of the cavity losses.”

*Page 3, line 35: for completeness you might also want to cite a recent paper on the measurement of the spectrum and absorption cross sections of the electronic transition of HO<sub>2</sub> (and DO<sub>2</sub>) around 1420 nm: E. Assaf et al. JQSRT 201, 161-170 (2017)*

The recent paper mentioned by the referee is now cited for completeness:

“Fittschen and co-workers have used the CRDS technique to perform time-resolved measurements of the HO<sub>2</sub> radicals, generated by pulsed laser photolysis in a flow cell, to extract spectroscopic (Thiebaud et al., 2007;Thiebaud and Fittschen, 2006;Ibrahim et al., 2007;Parker et al., 2011;Assaf et al., 2017) and kinetic (Thiebaud and Fittschen, 2006;Morajkar et al., 2014) information.”

The text has been also corrected according to the following suggestions of the referee:

*Page 4, line 5: long time averaging times*

Now it reads: “long averaging times”

*Page 4, line 31: HO<sub>2</sub>*

Now: HO<sub>2</sub>

*Page 11, line 30 : in in*

One of them has been deleted.

**Author response to anonymous referee # 2 on “An intercomparison of HO<sub>2</sub> measurements by Fluorescence Assay by Gas Expansion and Cavity Ring–Down Spectroscopy within HIRAC (Highly Instrumented Reactor for Atmospheric Chemistry)” by L. Onel et al.**

Note: The changes in the manuscript addressing the comments of the referee # 2 are highlighted in yellow below.

*Q1. Page 7: Although Winiberg et al. demonstrated that the calibration factor derived from the self-reaction of HO<sub>2</sub> is independent of the water vapor concentration (when the rate constant for the HO<sub>2</sub>+HO<sub>2</sub> reaction accounts for the water dependence of the reaction), the LIF-FAGE calibration factor is sensitive to the water vapor concentration due to quenching of the OH fluorescence. This should be clarified and the dependence of the calibration factor on the concentration of water should be explicitly given. Did the authors calibrate the FAGE instrument using the flow tube method under the water vapor conditions typically used in the HIRAC chamber?*

The FAGE instrument was not calibrated using the flow tube method under the typical H<sub>2</sub>O vapour concentrations within the chamber ( $10^{13} - 10^{14}$  molecule cm<sup>3</sup>) as under such dry conditions the generated [HO<sub>2</sub>] would be below the detection limit of FAGE ( $\sim 8 \times 10^5$  molecule cm<sup>-3</sup> for S/N = 2 and 2 min averaging time). As described in Sect. 2.3.1 of the main manuscript Winiberg et al. (2015) reported that the FAGE calibration factor for HO<sub>2</sub> ( $C_{HO_2}$ ) obtained by the flow tube calibration using high water vapour concentrations is in good agreement with  $C_{HO_2}$  obtained by the kinetic method of calibration in relatively dry conditions in HIRAC. A similar result was obtained in this work:  $C_{HO_2} = (2.6 \pm 0.4) \times 10^{-7}$  counts cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup> mW<sup>-1</sup> (flow tube calibration; ([H<sub>2</sub>O]  $\sim 7.5 \times 10^{16}$  molecule cm<sup>3</sup>) and  $C_{HO_2} = (2.4 \pm 0.5) \times 10^{-7}$  counts cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup> mW<sup>-1</sup> (kinetic decay method; [H<sub>2</sub>O] =  $10^{13} - 10^{14}$  molecule cm<sup>3</sup>). Calculations using the collisional quenching rate coefficient of the OH excited state ( $A^2\Sigma^+ (\nu' = 0)$ ) by H<sub>2</sub>O,  $k_{Q(H_2O)} = 6.91 \times 10^{-10}$  cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup>, (Bailey et al., 1999) and [H<sub>2</sub>O] in the LIF detection cell during the calibration using the flow tube ( $\sim 2.4 \times 10^{14}$  molecule cm<sup>-3</sup>) resulted in only  $\sim 1\%$  lower fluorescence quantum yield relative to the value determined in the absence of H<sub>2</sub>O. As Sect. 2.3.1 (the text below) mentions that Winiberg et al. (2015) found a relatively invariant  $C_{HO_2}$  between [H<sub>2</sub>O] in the two calibration methods we think that no modification of the text is necessary.

“Winiberg et al. have shown that  $C_{HO_2}$  is relatively invariant between the high water vapour concentrations of the flow tube calibration method ([H<sub>2</sub>O]  $\sim 7 \times 10^{16}$  molecule cm<sup>-3</sup>) and the relatively dry conditions in HIRAC ([H<sub>2</sub>O]  $\sim 10^{13} - 10^{14}$  molecule cm<sup>-3</sup>) for the HO<sub>2</sub> recombination method.”

*Q2. Page 9: Why were the FAGE measurements across the diameter of the HIRAC chamber done using different HO<sub>2</sub> radical sources compared to the Cl<sub>2</sub> radical source used for the main experiments?*

In order to investigate into any [HO<sub>2</sub>] gradient across the HIRAC radius, HO<sub>2</sub> in steady-state was generated (for as long as possible). The photolytic mixtures used in the FAGE measurements across the chamber width have been chosen to generate a constant concentration of HO<sub>2</sub> over longer times than the photolysis of the Cl<sub>2</sub>/CH<sub>3</sub>OH/O<sub>2</sub> mixtures. The latter yield higher concentrations, but these start to change soon after photolysis has begun. Therefore, we think that no modification of the text is necessary.

*Q3. Pages 18-19: The authors should clarify the method used to generate the linear fits shown in Figures 8 and 9. Are they unweighted linear regressions, or a bivariate weighted fit that takes into account the corresponding uncertainties associated with each measurement?*

The linear fits shown in Figure 8b and 9b represent unweighted linear regressions.

Now the captures of the Figures 8b and 9b clarify the method used:

“Figure 8b ... Linear **unweighted** fits of the data generated gradients ...”

## Abstract.

The HO<sub>2</sub> radical was monitored simultaneously using two independent techniques in the Leeds HIRAC atmospheric simulation chamber at room temperature and total pressures of 150 mbar and 1000 mbar of synthetic air. In the first method, HO<sub>2</sub> was measured indirectly following sampling through a pinhole expansion to 3 mbar when sampling from 1000 mbar and 1 mbar when sampling from 150 mbar, with subsequent addition of NO to convert it to OH which was detected via laser-induced fluorescence spectroscopy using the FAGE (fluorescence assay by gas expansion) technique. The FAGE method is used widely to measure HO<sub>2</sub> concentrations in the field, and was calibrated using the 185 nm photolysis of water vapour in synthetic air with a limit of detection at 1000 mbar of  $1.6 \times 10^6$  molecule cm<sup>-3</sup> for an averaging time of 30 s. In the second method, HO<sub>2</sub> was measured directly and absolutely without the need for a calibration using Cavity Ring Down Spectroscopy (CRDS) with the optical path across the entire ~ 1.4 m width of the chamber, with excitation of the first O-H overtone at 1506.43 nm using a diode laser, and with a sensitivity determined from an Allan deviation plot of  $3.0 \times 10^8$  and  $1.5 \times 10^9$  molecule cm<sup>-3</sup> at 150 mbar and 1000 mbar, respectively, for an averaging period of 30 s. HO<sub>2</sub> was generated in HIRAC by the photolysis of Cl<sub>2</sub> using black lamps in the presence of methanol in synthetic air and was monitored by FAGE and CRDS for ~ 5–10 minute periods with the lamps on and also during the HO<sub>2</sub> decay after the lamps were switched off. At 1000 mbar total pressure the correlation plot of [HO<sub>2</sub>]<sub>FAGE</sub> versus [HO<sub>2</sub>]<sub>CRDS</sub> gave an average gradient of  $0.84 \pm 0.08$  for HO<sub>2</sub> concentrations in the range ~ 4–100 × 10<sup>9</sup> molecule cm<sup>-3</sup> while at 150 mbar total pressure the corresponding gradient was  $0.90 \pm 0.12$  on average for HO<sub>2</sub> concentrations in the range ~ 6–750 × 10<sup>8</sup> molecule cm<sup>-3</sup>. For the period after the lamps were switched off, the second-order decay of the HO<sub>2</sub> FAGE signal via its self-reaction was used to calculate the FAGE calibration constant for both 150 and 1000 mbar total pressure. This enabled a calibration of the FAGE method at 150 mbar, an independent measurement of the FAGE calibration at 1000 mbar, and an independent determination of the HO<sub>2</sub> cross section at 1506.43 nm,  $\sigma_{\text{HO}_2}$ , at both pressures. For CRDS, the HO<sub>2</sub> concentration obtained using  $\sigma_{\text{HO}_2}$  determined using previous reported spectral data for HO<sub>2</sub> and the kinetic decay of HO<sub>2</sub> method agreed to within 20 and 12 % at 150 and 1000 mbar, respectively. For the FAGE method a very good agreement (difference within 8 %) has been obtained at 1000 mbar between the water vapour calibration method and the kinetic decay of the HO<sub>2</sub> fluorescence signal method. This is the first intercomparison for HO<sub>2</sub> between FAGE and CRDS methods, and the good agreement between HO<sub>2</sub> concentrations measured using the indirect FAGE method and the direct CRDS method provides a validation for the FAGE method, which is used widely for field measurements of HO<sub>2</sub> in the atmosphere.

## 1 Introduction

The hydroperoxy radical, HO<sub>2</sub>, plays a central role in the chemistry of the atmosphere (Levy, 1971) and is a significant reactive species in several media such as hydrocarbon combustion (Zador et al., 2011; Blocquet et al., 2013; Djehiche et al., 2014),

atmospheric pressure plasmas (Gianella et al., 2016) and dielectric barrier discharges used to remove volatile organic compounds (VOCs) in air (Blin-Simiand et al., 2016). In the troposphere, HO<sub>2</sub> is generated directly by the reaction of OH radical with CO in the presence of O<sub>2</sub> (R1) and indirectly by the oxidation of larger VOCs (Reactions R2–R4) (Lu et al., 2012).

Ambient concentrations of HO<sub>2</sub> have been measured in a number of field campaigns and it has been found that maximum daytime concentrations are typically a few 10<sup>8</sup> molecule cm<sup>-3</sup> (Stone et al., 2012; Heard and Pilling, 2003). With a typical lifetime in clean air of ~ 1–2 min, HO<sub>2</sub> radicals participate in rapid chemical cycling at the heart of tropospheric oxidation, hence HO<sub>2</sub> is one of the best targets for chemical models to compare with field data. HO<sub>2</sub> is converted back to OH through several different pathways. In unpolluted environments, its self-reaction and reaction with RO<sub>2</sub> are the major loss pathways for HO<sub>2</sub> via Reactions (R5) + (R6) and (R7):

The reaction of HO<sub>2</sub> with NO dominates HO<sub>2</sub> loss in anthropogenically influenced environments and constitutes the main tropospheric *in situ* source of O<sub>3</sub> by Reactions (R8)–(R10).

In the marine boundary layer the reaction of HO<sub>2</sub> with halogen oxides, XO (X = Br, I), is also an important OH regeneration reaction (Bloss et al., 2005) :

In addition, OH can be reformed from HO<sub>2</sub> via the relatively slow reaction with ozone:

Because of its importance in various environments, HO<sub>2</sub> has been measured in laboratory experiments by a variety of spectroscopic methods. Early laboratory work studying the kinetics of HO<sub>2</sub> reactions used UV absorption near 220 nm to monitor HO<sub>2</sub> with detection limits of ~ 6 × 10<sup>11</sup> molecule cm<sup>-3</sup> (Kircher and Sander, 1984). The absorption spectrum of HO<sub>2</sub> in this region is broad, structureless and often overlapped by other species present in the system, such as RO<sub>2</sub> radicals and H<sub>2</sub>O<sub>2</sub> (produced by the HO<sub>2</sub> self-reaction (Reactions (R5) + (R6))), hence UV absorption spectroscopy is a relatively unselective

technique. As the HO<sub>2</sub> absorption spectrum in the infrared (IR) is more structured than in the UV region, the selectivity of the IR absorption methods is higher. Although the near IR range offers weaker absorption bands than the fundamental vibrational bands in the mid IR region (Yamada et al., 1983; Zahniser and Stanton, 1984) near IR lasers, detectors and optical components offer an improved performance over those in the mid IR. Therefore, more recent advances in the direct detection of HO<sub>2</sub> have been made by the development of absorption techniques in the near IR, typically using diode laser absorption via the first vibrational overtone of the O-H stretch, to monitor HO<sub>2</sub> by cavity absorption methods (Djehiche et al., 2011; Djehiche et al., 2014; Gianella et al., 2016; Bell et al., 2012) or conventional multi-pass/long-pass absorption spectroscopy (Tang et al., 2010) sometimes in combination with wavelength modulation spectroscopy (Taatjes and Oh, 1997; Christensen et al., 2004) or two-tone frequency modulation spectroscopy (Schocker et al., 2007; DeSain et al., 2003). The use of methods such as frequency modulation and intracavity absorption improves sensitivity, with typical detection limits in the range  $\sim 10^9$ – $10^{11}$  molecule cm<sup>-3</sup>. A recent addition to the spectroscopic techniques used for HO<sub>2</sub> detection in laboratory is mid IR Faraday rotation spectroscopy, which has been employed for *in situ* measurements of HO<sub>2</sub> at atmospheric pressure in combustion studies using dimethyl ether to obtain a 1  $\sigma$  concentration detection limit of 0.1 ppmv ( $1.15 \times 10^{12}$  molecule cm<sup>-3</sup> at 623 K) (Brumfield et al., 2013; Kurimoto et al., 2015). Whilst allowing wide applications for spectroscopic and kinetic applications these detection limits do not allow for the detection of HO<sub>2</sub> under atmospheric conditions where concentrations are typically around  $10^8$  molecule cm<sup>-3</sup> (Heard and Pilling, 2003).

Cavity ring-down spectroscopy (CRDS) using the OH overtone vibrational band (2,0,0)–(0,0,0) of the ground electronic state  $\tilde{X}^2A''$  (the  $2\nu_1$  band is centred at  $6648.9$  cm<sup>-1</sup> *i.e.*  $\sim 1504$  nm (Thiebaud et al., 2007)) of HO<sub>2</sub> has been applied in a number of studies to detect HO<sub>2</sub> at reduced pressure (Djehiche et al., 2014; Liu et al., 2008). The CRDS technique (Brown, 2003; O'Keefe and Deacon, 1988; Wheeler et al., 1998) is well established and consists in trapping a laser beam within a high finesse optical resonator formed by two highly reflective dielectric mirrors. If the laser frequency matches one of the cavity resonance frequencies, optical power within the resonator quickly builds up, and a fraction of the circulating power leaks out through one mirror. **A photodetector located at the back of this mirror measures the exponential decay in the light intensity** ('ring-down') with a time constant that is a measure of the cavity losses. If an absorbing gas is introduced into the cavity, the ring-down time will decrease due to the additional absorption loss. The concentration of the absorbing species, [A], is related to the difference in ring-down times via (O'Keefe and Deacon, 1988):

$$[A] = \frac{1}{\sigma c} \left( \frac{1}{\tau} - \frac{1}{\tau_0} \right), \quad (1)$$

where  $\sigma$  is the absorption cross section of the species A,  $c$  is the velocity of light,  $\tau$  and  $\tau_0$  are the ring-down times in the presence and absence of the absorber.

Fittschen and co-workers have used the CRDS technique to perform time-resolved measurements of the HO<sub>2</sub> radicals, generated by pulsed laser photolysis in a flow cell, to extract spectroscopic (Thiebaud et al., 2007; Thiebaud and Fittschen, 2006; Ibrahim et al., 2007; Parker et al., 2011; **Assaf et al., 2017**) and kinetic (Thiebaud and Fittschen, 2006; Morajkar et al., 2014) information. The majority of the experiments have been conducted at room temperature to provide absorption cross sections and spectral line strengths at 50 Torr of He (Thiebaud et al., 2007; Parker et al., 2011) and air-broadening coefficients of the spectral lines (Ibrahim et al., 2007) (by using pressures between 7 and 160 Torr) for HO<sub>2</sub> in the  $2\nu_1$  band. The most significant absorption feature in the wavelength range  $6604 - 6696$  cm<sup>-1</sup> has been found at  $6638.20$  cm<sup>-1</sup> (*i.e.*  $1506.43$  nm), with a Doppler limited peak cross section of  $\sigma_D = 4.2 \times 10^{-19}$  cm<sup>2</sup> molecule<sup>-1</sup> (no errors quoted), in very good agreement with the conventional multi-pass study performed by Tang et al. (2010), which reports  $\sigma_D = (4.3 \pm 1.1) \times 10^{-19}$  cm<sup>2</sup> molecule<sup>-1</sup> at the same wavenumber. Fittschen and co-workers calculated a minimum detectable concentration of HO<sub>2</sub> of  $3.2 \times 10^9$  molecule cm<sup>-3</sup> for detection at  $6638.20$  cm<sup>-1</sup> with a 1 Hz detection bandwidth (1 s integration time) (Thiebaud et al., 2008).

Despite its significance, at present HO<sub>2</sub> is not typically measured directly in the atmosphere. Previous direct measurements of HO<sub>2</sub> were performed by the Matrix Isolation Electron Spin Resonance (MIESR) technique (Mihelcic et al., 1978), but this

method has been retired and was characterised by **long averaging times** (30 min (Fuchs et al., 2009)). However, recently Chemical Ionisation Mass Spectrometry (CIMS) employing  $\text{Br}^-$  as a reagent ion has been used for direct  $\text{HO}_2$  measurements with a limit of detection of  $\sim 1.7 \times 10^7$  molecule  $\text{cm}^{-3}$  for a 1 min integration time (Sanchez et al., 2016). Laser-induced fluorescence (LIF) at low pressure, known as Fluorescence Assay by Gas Expansion (FAGE) (Stone et al., 2012; Heard and Pilling, 2003), is most commonly used for the measurements of OH and  $\text{HO}_2$ . However,  $\text{HO}_2$  is not detected directly, rather it is converted to OH by reaction with added NO (R8) followed by OH on-resonance LIF at 308 nm (Hard et al., 1992). FAGE is a sensitive technique, with a typical detection limit for  $\text{HO}_2$  of  $(5\text{--}10) \times 10^5$  molecule  $\text{cm}^{-3}$ , depending on the individual instrument, averaging time and the desired signal-to-noise ratio (Stone et al., 2012). Another indirect method uses CIMS to determine the sum of  $\text{HO}_2$  and the organic peroxy radicals ( $\text{RO}_2$ ),  $[\text{HO}_2] + \sum_i [\text{RO}_{2,i}]$ , or separately  $[\text{HO}_2]$  depending on the flows of the NO and  $\text{SO}_2$  reagents (Hanke et al., 2002; Edwards et al., 2003). A typical detection limit for the indirect CIMS (sometimes referred to as per-CIMS or ROXMAS) method is  $1 \times 10^7$  molecule  $\text{cm}^{-3}$  for 15 s averaging time (Hanke et al., 2002; Edwards et al., 2003). The  $\text{HO}_2$  concentrations at an urban site have also been recently derived from observations of  $\text{HO}_2\text{NO}_2$  by using CIMS with  $\text{I}^-(\text{H}_2\text{O})_n$  as a reagent ion combined with measurements of  $\text{NO}_2$  by cavity attenuated phase shift spectroscopy (Chen et al., 2017). The Peroxy Radical Chemical Amplifier (PERCA) method has been used for many years to determine the sum  $[\text{HO}_2] + \sum_i [\text{RO}_{2,i}]$  by using NO and CO to generate  $\text{NO}_2$ , which is amplified by a chain reaction and subsequently measured through a range of methods, such as luminol fluorescence, LIF or cavity absorption methods, with typical detection limits in the range of  $1\text{--}2.5 \times 10^7$  molecule  $\text{cm}^{-3}$  in a 1 min time-period (Cantrell and Stedman, 1982; Cantrell et al., 1984; Miyazaki et al., 2010; Green et al., 2006; Chen et al., 2016). A recently developed method is  $\text{RO}_x\text{LIF}$ , which is an extension of FAGE, enabling  $\text{HO}_2$  and  $\sum_i [\text{RO}_{2,i}]$  to be measured separately (Fuchs et al., 2008), and with good sensitivity ( $\sim 2.5 \times 10^6$  molecule  $\text{cm}^{-3}$  detection limit in 1 min). The concentration of the initial  $\text{HO}_2$  is determined by subtracting the separate direct measurement of [OH] from the indirect measurement of  $[\text{HO}_x] = [\text{OH}] + [\text{HO}_2]$  by converting  $\text{HO}_x$  to  $\text{HO}_2$  through addition of CO followed by the  $\text{HO}_2$  conversion into OH in the FAGE detection chamber.

Whilst FAGE has the appropriate sensitivity and time resolution for atmospheric monitoring, there are two issues that could potentially cause systematic errors with this technique. First, FAGE is not an absolute method and hence requires a calibration which may lead to a source of error. Secondly, it is not a direct technique, but requires chemical conversion to another species, OH, which is subsequently detected by LIF spectroscopy, and hence may be subject to additional uncertainties associated with the conversion, i.e. could be prone to interferences arising from the conversion of species other than  $\text{HO}_2$  to OH. One known interference of this type is the conversion of beta-hydroxyalkylperoxy radicals (Fuchs et al., 2011; Whalley et al., 2013). For calibration, the most common method to generate accurate known concentrations of OH and  $\text{HO}_2$  uses the photolysis of water vapour at 184.9 nm in zero air employing a mercury pen-ray lamp:

The water photolysis method has been used for many years for the calibration of FAGE instruments (Stone et al., 2012; Heard and Pilling, 2003). The reliability of the method has been confirmed by intercomparisons with alternative methods of calibration for OH and  $\text{HO}_2$ . For  $\text{HO}_2$ , the kinetics of the second-order decay of  $\text{HO}_2$  via its self-reaction has been observed in HIRAC (Highly Instrumented Reactor for Atmospheric Chemistry) to obtain a FAGE calibration factor in good agreement with the one determined by using the water photolysis method for a pressure in the fluorescence detection cell between 1.4–3.8 mbar (Winiberg et al., 2015).

Intercomparisons between different  $\text{HO}_2$  instruments have been used to probe the susceptibility of instruments towards any bias, for example via the calibration methodology used and potential interferences. In 2005, three FAGE instruments measured  $\text{HO}_2$  during the  $\text{HO}_x\text{Comp}$  campaign, showing variable agreement with correlation slopes between 0.69 to 1.26 in the SAPHIR

(Simulation of Atmospheric Photochemistry in a large Reaction Chamber) chamber and sometimes worse correlations in ambient air (Fuchs et al., 2010). Agreement whilst detecting HO<sub>2</sub> in the same location for various designs of the FAGE technique increases the confidence in the use of the FAGE method, but such intercomparisons are rare. A field intercomparison between FAGE and CIMS measurements of HO<sub>2</sub> gave agreement within 40% (Ren et al., 2003) while a subsequent intercomparison between RO<sub>x</sub>LIF and MIESR techniques for HO<sub>2</sub> in the SAPHIR chamber resulted in a very good agreement, with correlation slopes of  $0.98 \pm 0.08$  ( $1\sigma$ ) (Fuchs et al., 2009).

This paper reports the first intercomparison between FAGE and CRDS measurements of HO<sub>2</sub>. The experiments have been performed at room temperature and two different pressures: 150 mbar and 1000 mbar within the HIRAC atmospheric simulation chamber (Glowacki et al., 2007). For measurements at 1000 mbar, FAGE was calibrated using the conventional water vapour photolysis method, whilst at 150 mbar the FAGE calibration constant was determined by studying the kinetics of HO<sub>2</sub> via its self-reaction, where the time constant of the second-order decay depends on the absolute, initial concentration of HO<sub>2</sub>, [HO<sub>2</sub>]<sub>0</sub>. The CRDS technique was chosen **to confirm the HO<sub>2</sub> measurements by the FAGE method as CRDS is a direct absorption method that does not require the chemical conversion of HO<sub>2</sub> to another species**. Reported here are the first CRDS measurements of HO<sub>2</sub> carried out in an atmospheric simulation chamber. The newly constructed CRDS spectrometer consists of a high finesse linear optical cavity set up across the chamber for the *in situ* direct HO<sub>2</sub> detection over a distance of ~ 1.4 m between two highly reflective dielectric mirrors ( $R > 0.9999$ ; typical ring-down time  $\tau = 230$   $\mu$ s), which results in ~ 70 km effective absorption path length. The use of a homogeneously mixed chamber allowed the same [HO<sub>2</sub>] to be sampled by the two techniques. A further advantage of the use of HIRAC is that the experiments can be performed under controlled conditions which produce approximately constant [HO<sub>2</sub>] at different levels and, in addition, can generate HO<sub>2</sub> temporal decays by turning off the UV lamps employed for the generation of the radicals in the chamber. The CRDS spectrometer used diode laser light at 1506.43 nm (vacuum wavelength, corresponding to  $6638.2$   $\text{cm}^{-1}$ ) to probe HO<sub>2</sub> at its peak absorption in the  $2\nu_1$  band. The HO<sub>2</sub> cross sections at 1506.43 nm,  $\sigma_{\text{HO}_2}$ , at 150 mbar and 1000 mbar, respectively are estimated using the reported HO<sub>2</sub> spectra and pressure-broadening coefficients for the transitions contributing to  $\sigma_{\text{HO}_2}$  (Thiebaud et al., 2007) and are compared with values obtained by analysing the second-order temporal decays of HO<sub>2</sub> monitored by CRDS and FAGE.

## 2 Experimental

### 2.1 HO<sub>2</sub> generation in HIRAC

Experiments were conducted in HIRAC, at 295 K and in 150 mbar and 1000 mbar of synthetic air obtained by mixing high purity oxygen (BOC, > 99.999 %) and nitrogen (BOC, > 99.998 %) in the ratio of O<sub>2</sub>:N<sub>2</sub> = 1:4. HIRAC is a stainless steel cylinder with internal dimensions of 2.0 m length and 1.2 m diameter (Fig. 2a below), which was built with a number of flanges to allow for easy coupling of equipment and has been described in detail previously (Glowacki et al., 2007). Thorough mixing of the gas mixtures was achieved by four low-vibration circulation fans mounted in pairs at each end of the chamber. Methanol (Sigma Aldrich, HPLC grade,  $\geq 99.9$  %,  $(0.7 - 1.4) \times 10^{14}$  molecule  $\text{cm}^{-3}$  in the experiments at 150 mbar and  $(0.8 - 2.0) \times 10^{14}$  molecule  $\text{cm}^{-3}$  in the experiments at 1000 mbar) and molecular chlorine (Sigma Aldrich,  $\geq 99.5$  %,  $7 \times 10^{12} - 2.1 \times 10^{14}$  molecule  $\text{cm}^{-3}$  in the experiments at 150 mbar and  $(0.4 - 1.6) \times 10^{14}$  molecule  $\text{cm}^{-3}$  in the experiments at 1000 mbar) were delivered to the chamber. The chemistry generating HO<sub>2</sub> was initiated by the photolysis of Cl<sub>2</sub> using eight UV black lamps (Phillips, TL-D36W/BLB,  $\lambda = 350-400$  nm) housed in quartz tubes mounted radially inside the reactive volume (aligned parallel to the chamber longitudinal axis):

Two kinds of intercomparison studies have been performed: experiments where the UV lamps were turned on for 5 – 10 min to generate a slowly changing  $[\text{HO}_2]$  and then off to follow the  $\text{HO}_2$  decay (Sect. 3.5) and experiments where the lamps were alternately turned on for 2 – 3 min and then off for ~ 3 min to generate a series of three  $\text{HO}_2$  temporal decays followed by regeneration of the  $\text{HO}_2$ . Figures S7 and S8 in the supplementary information are examples of the series of  $\text{HO}_2$  decays measured at the two pressures.

## 2.2 FAGE instrument

Full details on the HIRAC FAGE instrument can be found in previous publications (Winiberg et al., 2016; Onel et al., 2017; Winiberg et al., 2015). In the FAGE method, gas was sampled from the HIRAC chamber via 50 mm diameter sampling inlet into a reduced pressure fluorescence cell where OH (either present in the HIRAC chamber or converted from  $\text{HO}_2$ ) was detected by LIF. Although capable of simultaneously determining OH and  $\text{HO}_2$ , only data from the  $\text{HO}_2$  measurements are described here.

In order to detect the  $\text{HO}_2$  radicals generated within HIRAC the FAGE instrument was coupled to the chamber through a custom-made ISO-K160 flange to sample the gas at ~ 230 mm from the chamber wall (Fig. 2a in Sect. 2.4). Under typical operating conditions, air was sampled at ~ 3 slm through a 1.0 mm diameter pinhole nozzle and passed down the inlet (length 280 mm, 50 mm diameter, although the length was varied in some experiments, see below) into the OH detection axis maintained at low pressure using a high capacity rotary pump-backed roots blower pumping system (Leybold, trivac D40B and ruvac WAU251). Concentrations of  $\text{HO}_2$  were measured simultaneously in a second detection axis ~300 mm downstream of the OH detection axis (internal pressure =  $(3.24 \pm 0.20)$  mbar when sampling from 1000 mbar). High purity NO (BOC, N2.5 nitric oxide) was added ~25 mm before the  $\text{HO}_2$  detection axis into the centre of the FAGE cell in the direction of gas flow through 1/8" diameter stainless steel tubing at a rate of 2.5 sccm (Brooks 5850S) converting a fraction of  $\text{HO}_2$  to OH. LIF with excitation at 308 nm ( $A^2\Sigma^+ (v'=0) \leftarrow X^2\Pi_i (v''=0)$  transition) was used to probe the OH radicals directly, and the resulting fluorescence was collected after passing through an interference filter ( $308.8 \pm 5.0$  nm). Laser light was generated using a pulsed Nd:YAG (JDSU Q201-HD) pumped dye laser (SIRAH Credo-Dye-N) operating at 5 kHz pulse repetition frequency and delivered via fibre optics to the fluorescence and reference cells. The laser power entering the  $\text{HO}_2$  fluorescence cell was typically 3 – 5 mW. A small portion of the laser light was directed into a reference cell where high concentrations of OH were generated from the thermal dissociation of water. The use of a reference cell maintained the laser at the optimum wavelength and the laser power reaching the reference cell was monitored to allow normalization of the fluorescence signal to fluctuations in laser power.

## 2.3 FAGE calibration for $\text{HO}_2$

### 2.3.1 Calibration at atmospheric pressure - $\text{H}_2\text{O}$ vapour photolysis

As described above and detailed in Winiberg et al. (2015), the photolysis of water at 184.9 nm is used to generate known concentrations of OH and  $\text{HO}_2$ . A humidified flow of zero air (40 SLM, BOC, BTCA 178) was flowed into a square cross-section flow tube with  $[\text{H}_2\text{O}]$  measured using a dew-point hygrometer (CR4, Buck Research Instruments). The collimated 184.9 nm output of a mercury lamp (LOT-Oriel, Pen-Ray) was introduced to the end of the flow tube to photolyse the water.

The gas output from the flow tube was directed towards the FAGE sampling inlet, where overfilling of the FAGE sampling inlet ensured no ingress of ambient air. A range of HO<sub>x</sub> concentrations were produced by changing the lamp current.

The HO<sub>x</sub> concentrations are given by:

$$[\text{OH}] = [\text{HO}_2] = [\text{H}_2\text{O}] \sigma_{\text{H}_2\text{O}, 184.9 \text{ nm}} \Phi_{\text{H}_2\text{O}} F_{184.9 \text{ nm}} \Delta t. \quad (2)$$

where  $\sigma_{\text{H}_2\text{O}, 184.9 \text{ nm}}$  is the photolysis cross-section of water at 184.9 nm,  $\Phi_{\text{OH}}$  is the quantum yield for OH formation (unity),  $F_{184.9 \text{ nm}}$  is the photon flux and  $\Delta t$  is the photolysis time. The photolysis cross-section and quantum yield are well known and the product  $F_{184.9 \text{ nm}} \Delta t$  is determined by N<sub>2</sub>O actinometry (Edwards et al., 2003). An example of a calibration plot is shown in the supplementary information (Fig. S1). The resultant average calibration constant was:

$$C_{\text{HO}_2} = (2.6 \pm 0.4) \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$$

where  $C_{\text{HO}_2}$  is defined by  $S_{\text{HO}_2} = C_{\text{HO}_2} [\text{HO}_2]$  and the error is a combination of systematic and statistical uncertainties at the  $1\sigma$  level. The resulting limit of detection (*LOD*) for a signal-to-noise ratio (*S/N*) of 2 and 2 minute averaging, was  $LOD = 7.8 \times 10^5 \text{ molecule cm}^{-3}$ . The value of the calibration constant is in very good agreement with the value obtained by using the kinetic decay method based on determination of HO<sub>2</sub> second-order recombination (Sect. S2 in the supplementary information and (Winiberg et al., 2015)) at 1000 mbar, which gives:  $C_{\text{HO}_2} = (2.4 \pm 0.5) \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$ . The principle behind the kinetic method of calibration is that the time constant of the second-order decay of HO<sub>2</sub> in the self-reaction is dependent upon its initial concentration, and hence its analysis offers an alternative way to calibrate the signal. Winiberg et al. have shown that  $C_{\text{HO}_2}$  is relatively invariant between the high water vapour concentrations of the flow tube calibration method ( $[\text{H}_2\text{O}] \sim 7 \times 10^{16} \text{ molecule cm}^{-3}$ ) and the relatively dry conditions in HIRAC ( $[\text{H}_2\text{O}] \sim 10^{13} - 10^{14} \text{ molecule cm}^{-3}$ ) for the HO<sub>2</sub> recombination method. Therefore, the average value of these methods is:  $\bar{C}_{\text{HO}_2, 1000 \text{ mbar}} = (2.5 \pm 0.5) \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$ .

### 2.3.2 Calibration at 150 mbar - kinetics of the HO<sub>2</sub> temporal decay

The kinetics of the temporal decay of HO<sub>2</sub> has been used as the calibration method of FAGE sampling from HIRAC at 150 mbar (fluorescence cell pressure =  $(1.0 \pm 0.1) \text{ mbar}$ ). This method was previously validated for HO<sub>2</sub> in HIRAC, where the FAGE calibration constant,  $C_{\text{HO}_2}$ , obtained from the analysis of the temporal decay of HO<sub>2</sub> (generated by the photolysis of HCHO, then the chamber lamps switched off) agreed with  $C_{\text{HO}_2}$  from the conventional water vapour photolysis method for a range of pressures in the fluorescence detection cell, 1.3–3.9 mbar (Winiberg et al., 2015). The variation of  $C_{\text{HO}_2}$  is small and linear and therefore the uncertainties associated with the short extrapolation for the internal cell pressure of 1.3 to 1.0 mbar are small.

In order to generate the second-order decays the chamber photolysis lamps were turned off. The HO<sub>2</sub> was consumed by the bimolecular and termolecular self-reactions (Reactions (R5) + (R6)) and removed by the first-order wall-loss. In order to investigate if HO<sub>2</sub> removal by the wall-loss is significant, the experimental data were fitted by two different equations. Eq. (3) assumes that the loss of HO<sub>2</sub> is due entirely to the overall self-reaction (Reactions (R5) + (R6)), i.e. without taking into account the wall-loss of HO<sub>2</sub>.

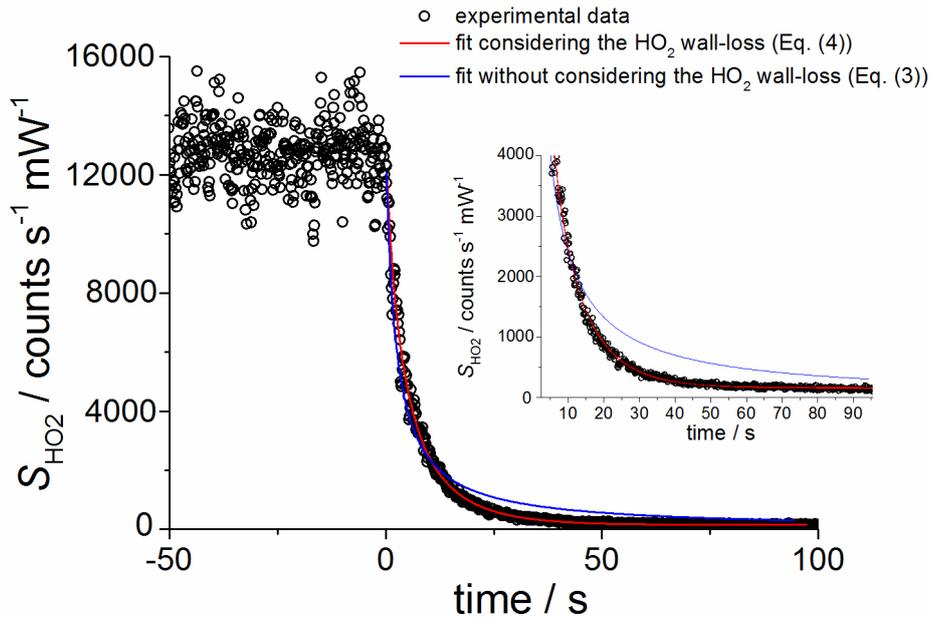

$$(S_{\text{HO}_2})_t = \left( \frac{1}{(S_{\text{HO}_2})_0} + \frac{2 \cdot k_{\text{self-r}, t}}{C_{\text{HO}_2}} \right)^{-1}, \quad (3)$$

where  $(S_{\text{HO}_2})_t$  is the fluorescence signal at reaction time  $t$ ,  $(S_{\text{HO}_2})_0$  is the signal at time  $t = 0$ , when the lamps were switched off and  $k_{\text{self-r}}$  is the overall HO<sub>2</sub> self-reaction rate coefficient. Eq. (4) includes the HO<sub>2</sub> wall-loss as a first-order process:

$$(S_{\text{HO}_2})_t = \left( \left( \frac{1}{(S_{\text{HO}_2})_0} + \frac{2 \cdot k_{\text{self-r.}}}{k_{\text{loss}} \cdot C_{\text{HO}_2}} \right) \times \exp(k_{\text{loss}} t) - \left( \frac{2 \cdot k_{\text{self-r.}}}{k_{\text{loss}} \cdot C_{\text{HO}_2}} \right) \right)^{-1}, \quad (4)$$

where  $k_{\text{loss}}$  is the rate coefficient describing the  $\text{HO}_2$  wall-loss.

Figure 1 shows an example of the experimental decay of  $S_{\text{HO}_2}$  with data averaged over 0.1 second (500 laser pulses) and the fits given by equations (3) and (4) above fixing  $k_{\text{self-r.}}$  to  $1.79 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ , according to the IUPAC recommendation (Atkinson et al., 2004), and with  $C_{\text{HO}_2}$  and  $k_{\text{loss}}$  floated. It is clear that wall-losses must be included in order to provide a good fit to the data, especially at later times ( $r^2 = 0.99$ ). This result is in agreement with previous  $\text{HO}_2$  calibrations where Eq. (4) was applied to analyse the kinetics of the  $\text{HO}_2$  decays generated in HIRAC (Winiberg et al., 2015). Therefore, Eq. (4) has been chosen to fit the experimental data. Nine  $\text{HO}_2$  decays were analysed, which yielded an average value of  $C_{\text{HO}_2} = (2.6 \pm 0.5) \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$ . Therefore,  $C_{\text{HO}_2, 150 \text{ mbar}} \cong C_{\text{HO}_2, 1000 \text{ mbar}}$  ( $\bar{C}_{\text{HO}_2, 1000 \text{ mbar}} = (2.5 \pm 0.5) \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$ ; Sect. 2.3.1) which agrees with the negligible change in  $C_{\text{HO}_2}$  with the decrease in the detection cell pressure found previously (Winiberg et al., 2015). The wall-loss rate coefficient obtained from the fit,  $k_{\text{loss}} = (0.09 \pm 0.02) \text{ s}^{-1}$ , has overlapping error limits with the range of values reported previously for  $\text{HO}_2$  in HIRAC,  $(0.03\text{--}0.07) \text{ s}^{-1}$  (Winiberg et al., 2015).

**Figure 1.** An example of temporal decay of the normalized FAGE  $\text{HO}_2$  signal with 0.1 second time resolution recorded at 295 K and 150 mbar mixture of  $\text{N}_2:\text{O}_2 = 4:1$  using  $\text{Cl}_2/\text{CH}_3\text{OH}$  and the black lamps (details given in the main text);  $[\text{Cl}_2]_0 \sim 3 \times 10^{13} \text{ molecule cm}^{-3}$  and  $[\text{CH}_3\text{OH}]_0 \sim 5 \times 10^{13} \text{ molecule cm}^{-3}$ . At time zero the photolysis lamps were turned off. Fitting Eq. (4) to this example trace (red line) gave  $C_{\text{HO}_2} = (2.45 \pm 0.06) \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$  ( $r^2 = 0.99$ ) while fitting Eq. (3) to the data (blue line) led to  $C_{\text{HO}_2} = (1.06 \pm 0.02) \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$  ( $r^2 = 0.95$ ) - statistical errors at  $1\sigma$  level. The inset shows the fit to the data using the two equations at later times. Note that the most significant source of the signal noise is the shot noise (Poisson noise), which grows with the number of photons counted by the detector.

### 2.3.3 FAGE measurements of HO<sub>2</sub> across the HIRAC diameter

In order to ensure that the point measurements of [HO<sub>2</sub>] with FAGE and the CRDS measurements of the average [HO<sub>2</sub>] across the width of the chamber (see Section 2.4) are comparable, investigations into any [HO<sub>2</sub>] gradient across the ~ 600 mm radius of the chamber were performed. HO<sub>2</sub> was generated either from the photolysis of formaldehyde at 270–320 nm (lamps: Philips TL40W/12 RS) in air at 150 mbar, which produced HO<sub>2</sub> by the reaction of O<sub>2</sub> with the H atoms and the HCO radicals generated by CH<sub>2</sub>O photolysis, or O<sub>3</sub> photolysis at 254 nm (lamps: GE G55T8 / OH 7G) followed by the reaction of the O(<sup>1</sup>D) generated with H<sub>2</sub>O to produce OH and, then by the reaction of OH with O<sub>3</sub> at 1000 mbar of air. An extended FAGE inlet of a length of ~ 520 mm was used to sample at separate locations up to 500 mm across HIRAC. At both pressures a constant [HO<sub>2</sub>] was found (within the 10% 1 $\sigma$  precision uncertainty of the measurement) at locations between ~ 100 and 500 mm from the wall while [HO<sub>2</sub>] gradually decreased between ~ 100 and 0 mm from the wall; the maximum ~ 16% decrease occurred when the sampling pinhole was flush with the wall. This result is in good agreement with previous studies (Winiberg et al., 2015) and means that the point measurements of the FAGE system can readily be compared with the CRDS results. In addition, investigations into the radiation field profile within HIRAC have been performed to show that the distribution of the light intensity varies by less than 15% in ~ 75% the chamber volume (Glowacki et al., 2007).

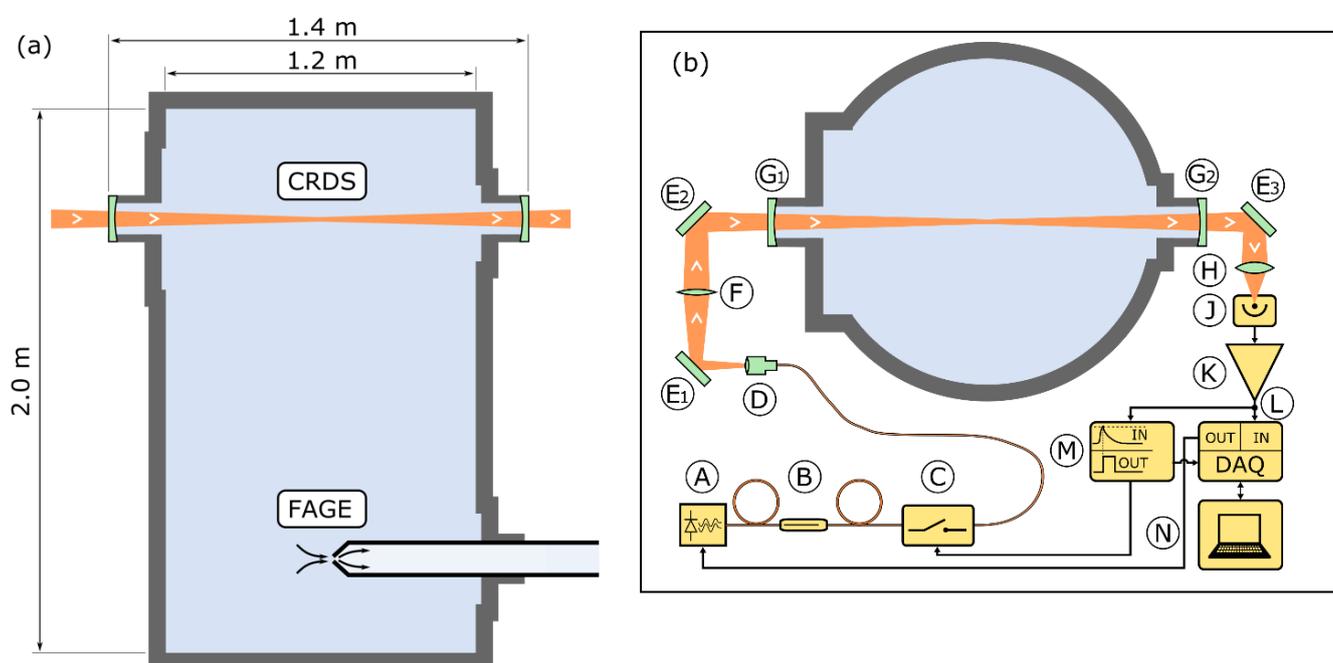

### 2.4 CRDS set-up

The CRDS spectrometer was set-up across the HIRAC diameter as shown in Fig. 2. To probe HO<sub>2</sub>, a diode laser beam at ~ 1506 nm is sent diametrically across the chamber (Fig. 2a). On either side there is a blank flange (ISO-K 500 on the injection side, ISO-K 160 on the detection side) onto which KF25 flanges have been welded so that a pair of home-made mirror mounts can be attached. A sketch of the cavity ring-down spectrometer is given in Fig. 2b. The  $\lambda \sim 1.5 \mu\text{m}$  distributed feedback (DFB) fibre pig-tailed diode laser [A] (NTT Electronics, NLK1S5GAAA) is held in a butterfly laser diode mount (Thorlabs LM14S2). Current to the laser diode and the built-in thermoelectric element is provided by a Thorlabs ITC502 driver. The single-mode fibre is connected to an inline optical isolator [B] (Thorlabs IO-H-1505APC), an acousto-optic modulator [C] (AOM, Gooch & Housego Fibre-Q T-M040-0.5C8J-3-F2S), and an adjustable fibre collimation package [D] (Thorlabs CFC-8X-C). The AOM is powered by a 0.5 W 40 MHz radio-frequency driver (Goch & Housego A35040-0.5W). The components [A], [B] and [C] lie on a small optical breadboard plate attached to HIRAC's support frame under the ISO-K 500 flange.

The free-space components [D], [E1], [E2] and [F] on the beam injection side (of the cavity) and [E3], [H], and [J] on the detection side are assembled with Thorlabs' 30-mm cage system, which in turn is supported by posts clamped onto HIRAC itself. This solution mitigates misalignment of the cavity axis relative to the beam axis under the effect of the mechanical deformation (pressure difference) of HIRAC and low-vibrations caused by the chamber's circulating fans. After the fibre collimator [D], a protected silver mirror [E1] (Thorlabs PF10-03-P01) is followed by a  $f = 250$  mm mode-matching lens [F] (Thorlabs LA1461-C) and a second identical mirror [E2]. The 1-inch diameter cavity mirrors [G1] and [G2] (Layertec, reflectivity:  $R > 0.9999$ , curvature radius: 1 m; the mode diameter varies from ~1 mm in the centre of the chamber to ~1.7 mm at the cavity mirrors) are housed in a pair of home-built mounts, which allow the mirrors to tilt slightly while maintaining a gas-tight seal. The mounts are both attached to KF25 flanges welded onto the ISO-K 500 flange on the beam injection side and onto a smaller ISO-K 160 flange on the detection side. The mirror [G1] can be moved by a few microns along the beam's axis by means of a piezoelectric transducer. The distance between the two mirrors is approximately 1.4 m. On the detection side, the mirror [E3] (Thorlabs PF10-03-P01) is followed by a  $f = 30$  mm focussing lens [H] (Thorlabs LA1805-C) and an InGaAs photodiode [J] (Thorlabs DET10C/M).

A low-noise transimpedance amplifier [K] (FEMTO DLPCA-200) sends the photodiode signal to the data acquisition unit [L] (DAQ, National Instruments USB-6361) and to a home-made latched comparator [M] ("trigger box"). The comparator

compares the photodiode signal with an adjustable threshold. When the signal crosses the threshold, the AOM is powered off (blocking the beam) and a trigger pulse is sent to the DAQ to start acquisition of the ring-down event. After a predefined duration (typically 5 ms), the AOM is powered back on and the system is ready for the next ring-down event. The digitized data are processed by a custom LabVIEW program (National Instruments) running on a laptop [N]. The program fits all acquired ring-down events with an exponential function and can run in two modes: *fixed wavelength* and *scan*. In fixed wavelength mode, the program was set-up to save all ring-down events as a function of time. A number of filters can be applied to the processed events to exclude outliers (caused for example by a dust particle passing through the beam) or false positives (when the acquisition is triggered by a transient noise spike), so that only legitimate ring-down events are taken into account. In scan mode, the wavelength of the laser is stepped (by changing the diode's temperature), each time a predefined number of ring-down events has been acquired and the mean ring-down time is determined as a function of wavelength. The laser emission wavelength has been calibrated using a wavemeter (Burleigh WA-1000). An example of the laser calibration plot ( $\lambda$  versus thermistor resistance) is shown in the supplementary information (Fig. S2). In addition, the calibration has been confirmed by reproducing the well-known transmission spectrum of water vapour in the range  $\sim 1506.1$ – $1506.9$  nm (Richard et al., 2012) at both 150 mbar and 1000 mbar (Fig. S3 in the supplementary information).

**Figure 2:** (a) Longitudinal (horizontal) section of HIRAC. The CRDS spectrometer probes the HO<sub>2</sub> concentration across the chamber's diameter, while the FAGE instrument samples the atmosphere in the chamber at one point. (b) Cross section of HIRAC. [A] Fibre-pigtailed DFB laser diode and mount; [B] inline optical isolator; [C] acousto-optic modulator (AOM); [D] adjustable fibre collimator; [E1]-[E3] silver mirrors; [F]  $f = 250$  mm mode-matching lens; [G1]-[G2] high reflectivity dielectric cavity mirrors; [H]  $f = 30$  mm focusing lens; [J] InGaAs photodiode; [K] transimpedance amplifier; [L] data acquisition unit; [M] latched comparator circuitry; [N] laptop running LabVIEW for data processing and storing.

### 3 Results

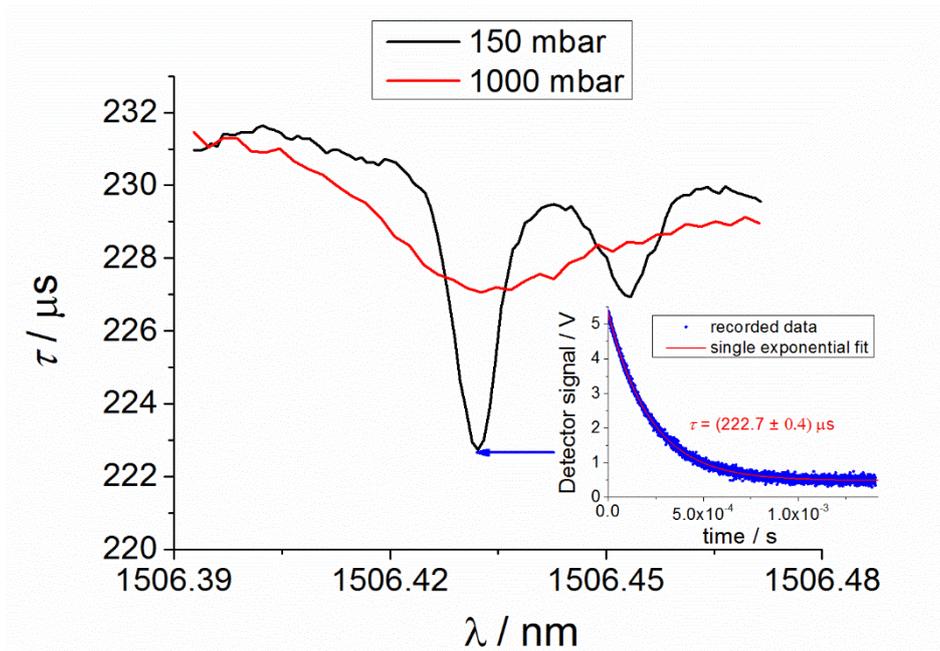

#### 3.1 HO<sub>2</sub> spectrum and comparison with literature

Figure 3 shows typical wavelength scans performed at the two HIRAC pressures. A higher spectral resolution was chosen for the measurement at 150 mbar ( $8 \times 10^{-4}$  nm per point and averaged for 50 ring-down events per point) than for the spectral measurement at 1000 mbar ( $2 \times 10^{-3}$  nm per point and averaged for 25 events per point) as at lower pressure the HO<sub>2</sub> absorption

spectrum is more structured, as shown in Fig. 3, owing to reduced pressure broadening. These choices lead to a recording time of  $\sim 9$  min at 150 mbar and 2 – 3 min at 1000 mbar. The maximum HO<sub>2</sub> absorption was recorded at 1506.43 nm (6638.20 cm<sup>-1</sup>; Fig. 3), where the strongest HO<sub>2</sub> absorption line in the range  $\sim 1493 - 1514$  nm ( $\sim 6604 - 6696$  cm<sup>-1</sup>) of the first overtone of the OH stretch has been reported to lie at (Thiebaud et al., 2007). Therefore, the FAGE – CRDS intercomparison experiments were run at fixed wavelength of 1506.43 nm. The spectral feature at 1506.43 nm consists of overlapping <sup>9</sup>Q<sub>3</sub>(*N*) transitions with *N* = 4 – 9, each of which is doubled by spin-rotation splitting, as originally assigned by Taatjes and co-workers (DeSain et al., 2003) who observed the absorption spectrum of the HO<sub>2</sub> in the 2  $\nu_1$  band at  $\sim 20$  mbar of He. Next to the 1506.43 nm feature there is a weaker HO<sub>2</sub> absorption line at 1506.45 nm, which has been assigned to the spin-rotation split <sup>9</sup>P<sub>0</sub>(6) transitions. As shown in Fig. 3 at 150 mbar there is little overlapping of the absorption lines, and the recorded features centred at 1506.43 nm and 1506.45 nm can be mainly attributed to the <sup>9</sup>Q<sub>3</sub>(*N*) and <sup>9</sup>P<sub>0</sub>(6) transitions, respectively. In contrast, the laser scans performed at 1000 mbar of air showed a relatively broad spectral feature centred at 1506.43 nm as the air-broadening of the HO<sub>2</sub> absorption lines resulted in a significant overlap of the 1506.43 nm line with the 1506.45 nm line and the other neighbouring HO<sub>2</sub> lines. At both pressures the minimum ring-down time,  $\tau$ , occurs at 1506.43 nm. The contribution of HO<sub>2</sub> to the decrease in the ring-down time at 1506.43 nm relative to  $\tau$  in the absence of reagents,  $\Delta\tau$  is  $\sim 50\%$  at 150 mbar and  $\sim 20\%$  at 1000 mbar, with the remaining contributions due to CH<sub>3</sub>OH. During the measurements, the background absorption decreased mainly due to the consumption of CH<sub>3</sub>OH by the CH<sub>3</sub>OH + Cl reaction (Reaction (R17)). [CH<sub>3</sub>OH] decreased by  $\sim 15\%$  during the scan at 150 mbar and  $\sim 10\%$  during the scan at 1000 mbar, as determined using FTIR measurements (supplementary information), to form CH<sub>2</sub>O through Reaction (R17) followed by (R18). Section S7 in the supplementary information shows that  $\sigma_{\text{CH}_3\text{OH}}$  is  $\sim 3$  times higher than  $\sigma_{\text{CH}_2\text{O}}$  at both pressures, hence  $\sim 30\%$  of the decrease in the absorption background due to the CH<sub>3</sub>OH consumption was counteracted by the formation of CH<sub>2</sub>O. The spectrum was measured from larger to smaller wavelengths (right to left), hence the decrease in background absorption with time (decreasing  $\lambda$ ) during a scan. The inset shows an example CRDS signal at 1506.43 nm and 150 mbar and the fit to the data performed by using Eq. (5) to extract  $\tau$ .

$$I_t = I_0 \exp(-\frac{t}{\tau}), \quad (5)$$

where  $I_t$  is the signal detected at time  $t$  and  $I_0$  is the signal at  $t = 0$ .

**Figure 3:** Typical laser scans of the ring-down time,  $\tau$ , as a function of wavelength, recorded for a HIRAC pressure of 150 mbar (black line) and 1000 mbar (red line) mixture of  $\text{N}_2:\text{O}_2 = 4:1$  and 295 K. For the sake of clarity the measurement at 1000 mbar was rescaled by adding 18  $\mu\text{s}$  to  $\tau$ .  $\text{HO}_2$  radicals were generated in the chamber using  $\text{CH}_3\text{OH}/\text{Cl}_2/\text{O}_2$  and black lamps;  $[\text{CH}_3\text{OH}]_0 = 7 \times 10^{13}$  molecule  $\text{cm}^{-3}$  and  $[\text{Cl}_2]_0 = 4 \times 10^{13}$  molecule  $\text{cm}^{-3}$  in the experiment at 150 mbar and  $[\text{CH}_3\text{OH}]_0 = 2 \times 10^{14}$  molecule  $\text{cm}^{-3}$  and  $[\text{Cl}_2]_0 = 2 \times 10^{14}$  molecule  $\text{cm}^{-3}$  in the experiment at 1000 mbar. The number of ring-down events averaged at each wavelength and the laser wavelength step were: 50 events and  $8 \times 10^{-4}$  nm (150 mbar) and 25 events and  $2 \times 10^{-3}$  nm (1000 mbar). The inset shows the ring-down trace acquired at 1506.43 nm and 150 mbar and the fit by Eq. (5) to extract  $\tau = (222.7 \pm 0.4)$   $\mu\text{s}$ .

### 3.2 Determination of the absorption cross section of $\text{HO}_2$ at 1506.43 nm as a function of pressure

The absorption cross section of  $\text{HO}_2$  at 1506.43 nm in the range 0–1100 mbar of air was computed by using a model which takes into account not only the feature centred at 1506.43 nm but also the contribution of the neighbouring transitions, due to the air-broadening of the absorption lines. The line centres  $\nu^*$  and strengths  $S$  (including the uncertainties  $\delta S$ ) of the  $\text{HO}_2$  transitions at 1506.43 nm and all the nearby transitions have been extracted from the spectra reported by Fittschen and co-workers at 50 Torr of He (Thiebaud et al., 2007). The reported absorption data was scaled so that the line strength of the main transition at 1506.43 nm becomes  $S = 7.09 \times 10^{-21}$   $\text{cm}^2 \text{cm}^{-1}$ , which we assume to be the correct value for that transition (Fittschen, 2017). The air-broadening coefficient,  $\gamma_{\text{air}}$ , was assumed to be the same for all transitions,  $0.115 \text{ cm}^{-1} \text{atm}^{-1} = 1.14 \times 10^{-4} \text{ cm}^{-1} \text{mbar}^{-1}$  (average value of 34  $\text{HO}_2$  transitions between 6631 and 6671  $\text{cm}^{-1}$  (Ibrahim et al., 2007)). For each transition (indexed by  $l$ ), an area-normalized Voigt profile  $\mathcal{V}(\nu; \nu_l^*, \Gamma_G, \Gamma_L(p))$ , centred at  $\nu_l^*$  (here  $\nu$  and  $\nu_l^*$  are wavenumbers) with Gaussian width  $\Gamma_G$  and Lorentzian width  $\Gamma_L(p)$ , was computed. The absorption cross section for  $\text{HO}_2$  at  $\nu$  is then given by Eq. (6).

$$\sigma_{\text{HO}_2}(\nu, p) = \sum_l S_l \mathcal{V}(\nu; \nu_l^*, \Gamma_G, \Gamma_L(p)) \quad (6)$$

In particular, the cross section for  $\text{HO}_2$  at the peak location  $\nu_{\text{pk}} = 6638.2 \text{ cm}^{-1}$  (1506.43 nm) is:

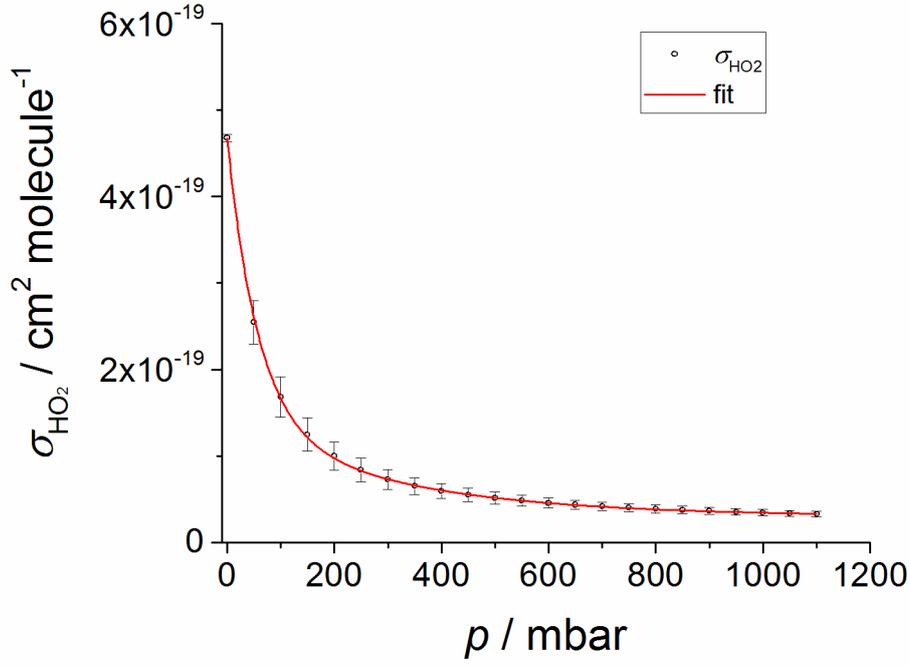

$$\sigma_{\text{HO}_2} = \sigma_{\text{HO}_2}(\nu_{\text{pk}}, p) = \sum_l S_l \mathcal{V}(\nu_{\text{pk}}; \nu_l^*, \Gamma_G, \Gamma_L(p)). \quad (7)$$

A plot of the calculated  $\sigma_{\text{HO}_2}$  as a function of pressure  $p$  and at 298 K is shown in Fig. 4 for pressures ranging from 0 to 1100 mbar in steps of 50 mbar. The error bars represent the uncertainties ( $\pm 1\sigma$ ) in  $\sigma_{\text{HO}_2}$  arising from the uncertainties in the pressure broadening parameter,  $\gamma_{\text{air}}$ , and in the line strengths,  $S$ . The error caused by  $\gamma_{\text{air}}$  was determined by computing  $\sigma_{\text{HO}_2}$  while linearly varying  $\gamma_{\text{air}}$  between the minimum and maximum value reported by Fittschen and co-workers (Ibrahim et al., 2007), i.e. between  $0.078 \text{ cm}^{-1} \text{atm}^{-1}$  and  $0.155 \text{ cm}^{-1} \text{atm}^{-1}$ . The uncertainty caused by the error in  $S$  was determined in a similar fashion, namely by computing  $\sigma_{\text{HO}_2}$  while linearly varying the line strengths between  $S_l - \delta S_l$  and  $S_l + \delta S_l$ . The simplest model that fits the simulated data is:

$$\sigma_{\text{HO}_2}(\nu_{\text{pk}}, p) = A_0 + A_1 \exp(-\lambda_1 p) + A_2 \exp(-\lambda_2 p). \quad (8)$$

The values of the fit parameters,  $A_0$ ,  $A_1$ ,  $A_2$ ,  $\lambda_1$  and  $\lambda_2$ , are given in Table S3 in the supplementary information.

The result of this work,  $\sigma_{\text{HO}_2, 150 \text{ mbar}} = (1.25 \pm 0.19) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$ , agrees very well with the value  $\sigma_{\text{HO}_2, 150 \text{ mbar}} = (1.29 \pm 0.23) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  calculated by using the equation computed by Tang et al. (2010) to describe the change in  $\sigma_{\text{HO}_2}$  at 1506.43 nm and 296 K with the increase in the pressure of air observed experimentally between 27 – 133 mbar using conventional multi-pass absorption spectroscopy.  $\sigma_{\text{HO}_2}$  has been determined previously only at low pressures, so there is no literature value to compare with our calculated value of  $\sigma_{\text{HO}_2, 1000 \text{ mbar}} = (3.44 \pm 0.37) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$ . Both  $\sigma_{\text{HO}_2, 150 \text{ mbar}}$  and  $\sigma_{\text{HO}_2, 1000 \text{ mbar}}$  were also determined by using the kinetic method to obtain  $[\text{HO}_2]$  presented in Sect. 3.3.

**Figure 4:** Absorption cross section of HO<sub>2</sub> at 1506.43 nm vs. pressure of air. The  $\sigma_{\text{HO}_2}$  values (circles) were computed using the line strengths of the HO<sub>2</sub> transitions contributing to the absorption at 1506.43 nm (Thiebaud et al., 2007) and the pressure broadening coefficients assumed to be the same for all transitions and equal to the average of the values reported for the spectral region between 1499 and 1508 nm ( $0.115 \text{ cm}^{-1} \text{ atm}^{-1} = 1.14 \times 10^{-4} \text{ cm}^{-1} \text{ mbar}^{-1}$ ) (Ibrahim et al., 2007) as explained in the main text. The red line is a fit of Eq. (7) to the calculated values. The extracted values of the equation parameters are shown in Table S3 in the supplementary information.

### 3.3 Determination of $\sigma_{\text{HO}_2}$ (1506.43 nm) using the kinetics of the HO<sub>2</sub> temporal decay

#### 3.3.1 $\sigma_{\text{HO}_2}$ (1506.43 nm) at 150 mbar

The kinetics of the temporal decay of HO<sub>2</sub> monitored by CRDS when the HIRAC lamps were extinguished, i.e. the HO<sub>2</sub> absorption coefficient at 1506.43 nm ( $\alpha_{\text{HO}_2}$ ) vs. time, has been used to determine  $\sigma_{\text{HO}_2}$  at 150 mbar. The absorption coefficient  $\alpha_{\text{HO}_2}$  (the product of the absorption cross section and the concentration) was computed using Eq. (9).

$$\alpha_{\text{HO}_2} = \frac{1}{c} \left( \frac{1}{\tau} - \frac{1}{\tau_0} \right), \quad (9)$$

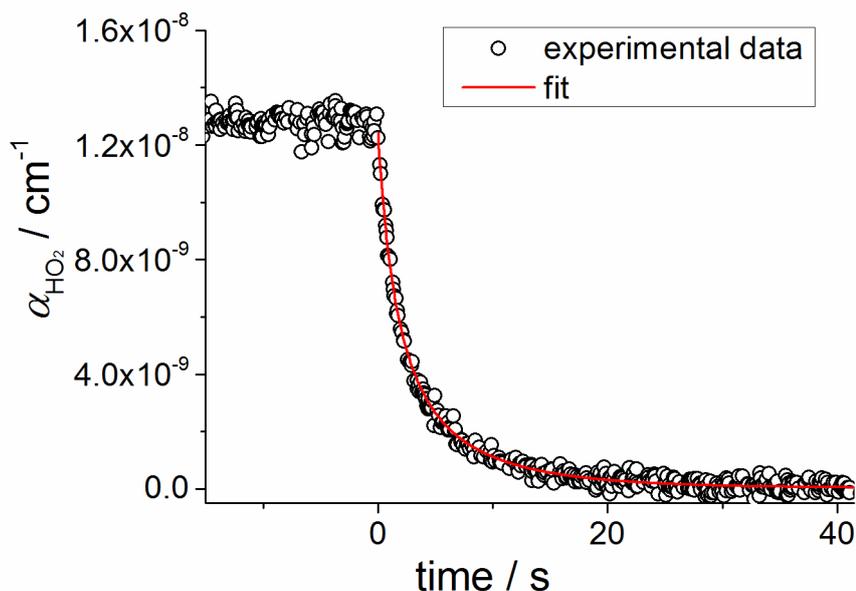

where  $c$  is the velocity of light and  $\tau$  and  $\tau_0$  are the ring-down times recorded with the lamps on and off, respectively.

The temporal decays of  $\alpha_{\text{HO}_2}$  were analysed to extract  $\sigma_{\text{HO}_2}$  in a similar fashion to how the FAGE signal decays were analysed to determine the FAGE calibration factor,  $C_{\text{HO}_2}$  (Eq. (4) in Section 2.3.2). Therefore, HO<sub>2</sub> decays were analysed using Eq. (10).

$$(\alpha_{\text{HO}_2})_t = \left( \left( \frac{1}{(\alpha_{\text{HO}_2})_0} + \frac{2 \cdot k_{\text{self-r.}}}{k_{\text{loss}} \cdot \sigma_{\text{HO}_2}} \right) \times \exp(k_{\text{loss}} t) - \left( \frac{2 \cdot k_{\text{self-r.}}}{k_{\text{loss}} \cdot \sigma_{\text{HO}_2}} \right) \right)^{-1}, \quad (10)$$

where  $k_{\text{self-r}}$  and  $k_{\text{loss}}$  have already been defined and  $(\alpha_{\text{HO}_2})_t$  and  $(\alpha_{\text{HO}_2})_0$  are the absorption coefficient at time  $t$  and  $t = 0$  (the time when the UV lamps were switched off). Eq. (10) was fitted to eight temporal traces (Fig. 5 shows an example) where the  $(\alpha_{\text{HO}_2})_0$  was varied by a factor of two to obtain an average  $\sigma_{\text{HO}_2} = (1.02 \pm 0.18) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  (see all the values in Table S4), where the error is a combination of systematic and statistical uncertainties at the  $1\sigma$  level. The statistical error was

only 3% showing that the analysis results are independent of  $[\text{HO}_2]_0$ . The obtained  $\sigma_{\text{HO}_2}$  is in broad agreement with  $\sigma_{\text{HO}_2} = (1.25 \pm 0.19) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  generated by the analysis presented in Section 3.2. The wall-loss rate coefficient,  $k_{\text{loss}}(\text{CRDS}) = (0.11 \pm 0.01) \text{ s}^{-1}$ , is slightly higher than  $k_{\text{loss}}(\text{FAGE}) = (0.09 \pm 0.02) \text{ s}^{-1}$ , determined by fitting the kinetic decays to calibrate the FAGE instrument. This result was expected as the FAGE instrument was measuring  $[\text{HO}_2]$  in the gas mixture sampled from one point at  $\sim 230 \text{ mm}$  from the HIRAC wall, while CRDS measured across the total width of the chamber (1200 mm) and the two 100 mm long system of flanges coupling the cavity mirrors to the chamber (Fig. 2). The investigations into the  $[\text{HO}_2]$  gradient across the HIRAC diameter (86% of the distance between the two cavity mirrors,  $L = 1400 \text{ mm}$ ) found a practically constant  $[\text{HO}_2]$  (Sect.2.3.3) due to the reactive mixture homogenized by the circulation fans. As the length of the systems of flanges coupling the mirrors, where the reactive mixture might not be homogenized, represented only 14% of  $L$ ,  $k_{\text{loss}}$  was considered uniform over the entire cavity length.

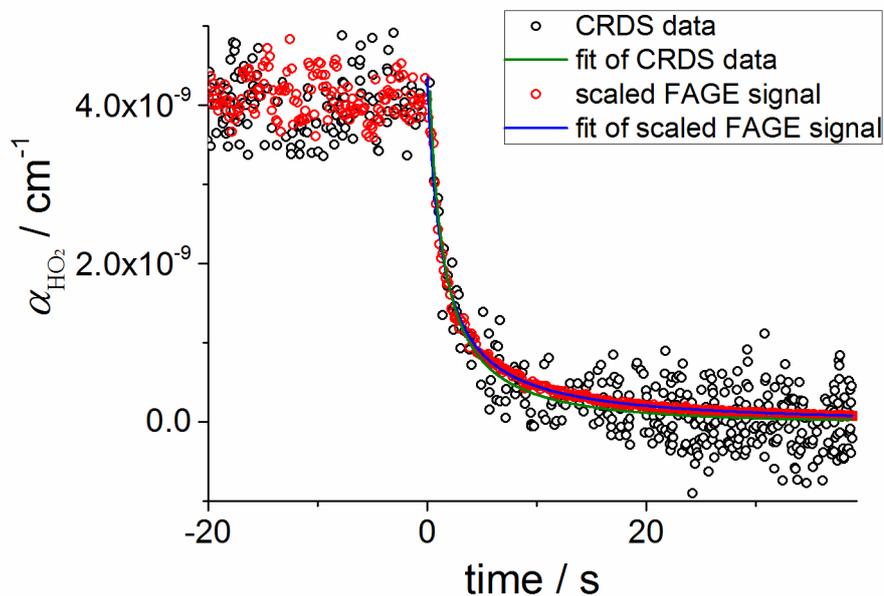

**Figure 5:** Second-order decay of the  $\text{HO}_2$  absorption coefficient at 1506.43 nm obtained by CRDS. Experiments performed in HIRAC at 295 K and 150 mbar mixture of  $\text{N}_2:\text{O}_2 = 4:1$ ;  $[\text{Cl}_2]_0 \sim 1.5 \times 10^{14} \text{ molecule cm}^{-3}$  and  $[\text{CH}_3\text{OH}]_0 \sim 1.0 \times 10^{14} \text{ molecule cm}^{-3}$ . At time zero the photolysis lamps were turned off. Fitting Eq. (10) to the data gave  $\sigma_{\text{HO}_2} = (1.02 \pm 0.05) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  (statistical error at  $1\sigma$  level).

Equation (9) employs the approximation that  $[\text{HO}_2]$  is constant along the entire length of the cavity,  $L$ . Future experiments using a flow of clean air in front of the both cavity mirrors are planned to protect them from (potential) contamination due to the reactive mixture and to test if the results of the analysis of the  $\text{HO}_2$  temporal decays remain unchanged by a virtual zero concentration of  $\text{HO}_2$  in front of the mirrors. Analysis was performed considering the worse-case scenario that no  $\text{HO}_2$  radicals were present over the two 100 mm distances between the cavity mirrors and the main HIRAC chamber, i.e.  $[\text{HO}_2] = 0$  over 14% of  $L$ . This analysis found the same wall-loss rate coefficient on average,  $k_{\text{loss}} = (0.11 \pm 0.01) \text{ s}^{-1}$ , as the average value obtained assuming that  $[\text{HO}_2]$  is constant across the entirety of  $L$ . The extracted  $\sigma_{\text{HO}_2}$ ,  $(1.18 \pm 0.22) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  on average, has overlapping overall errors (at the  $1\sigma$  level) with that found by the analysis where  $[\text{HO}_2]$  was considered homogeneous along the entire  $L$ ,  $(1.02 \pm 0.18) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  (further details in Sect. S9.2 in supplementary information).

### 3.3.2 $\sigma_{\text{HO}_2}$ (1506.43 nm) at 1000 mbar

The measured absorption coefficients  $\alpha_{\text{HO}_2, 1000 \text{ mbar}}$  were three times lower than  $\alpha_{\text{HO}_2, 150 \text{ mbar}}$  for the same  $\text{HO}_2$  concentrations, hence the signal-to-noise ratio decreased with increasing pressure (see Figs. 5 and 6 as examples of  $\alpha_{\text{HO}_2}$  vs. time at the two pressures). Therefore, the statistical uncertainties in the kinetic analysis of the  $\alpha_{\text{HO}_2}$  temporal decays were relatively high at 1000 mbar, having values of 19% in  $\sigma_{\text{HO}_2, 1000 \text{ mbar}}$  and 37% in  $k_{\text{loss}, 1000 \text{ mbar}}$  at  $1\sigma$  level on average. By comparison, the precision of the kinetic method at  $1\sigma$  level at 150 mbar was 3% in  $\sigma_{\text{HO}_2, 150 \text{ mbar}}$  and 10% in  $k_{\text{loss}, 150 \text{ mbar}}$ . In order to reduce the CRDS statistical uncertainties at 1000 mbar, the FAGE signal decays monitored at the same time with the  $\alpha_{\text{HO}_2}$  decays were used to determine  $\sigma_{\text{HO}_2, 1000 \text{ mbar}}$ . In this approach the fluorescence signal decays were scaled to overlap  $\alpha_{\text{HO}_2}$  vs. time by multiplying the FAGE signal by  $f = \frac{(\bar{\alpha}_{\text{HO}_2})_0}{(\bar{s}_{\text{HO}_2})_0}$ , where  $(\bar{\alpha}_{\text{HO}_2})_0$  and  $(\bar{s}_{\text{HO}_2})_0$  are the mean absorption coefficient and the mean FAGE signal before the UV lamps are turned off. Equation 10, where  $k_{\text{self-r.}}$  was fixed to  $2.85 \times 10^{-12} \text{ cm}^{-3} \text{ molecule}^{-1} \text{ s}^{-1}$  (Atkinson et al., 2004), was fitted to the scaled signal decays (Fig. 6 shows an example) to obtain an average  $\sigma_{\text{HO}_2} = (3.87 \pm 0.74) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  (further details in supplementary information), where the error limits are overall errors (19%) quoted at the  $1\sigma$  level. The value of  $\sigma_{\text{HO}_2(\text{FAGE})}$  agrees very well with the average absorption cross section obtained by fitting Eq. (10) to the temporal decays recorded by the CRDS system,  $\sigma_{\text{HO}_2(\text{CRDS})} = (3.68 \pm 0.99) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  (Sect. 9.3 in supplementary information), where the overall  $1\sigma$  uncertainty is 27%. Both values are in good agreement with  $\sigma_{\text{HO}_2} = (3.44 \pm 0.37) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  computed by the model described in Section 3.2, which considered the contribution of the air-broadened  $\text{HO}_2$  absorption lines (Thiebaud et al., 2007) to the overall cross section at 1506.43 nm. As the precision in  $\sigma_{\text{HO}_2(\text{FAGE})}$  (3%) is much higher than the precision in  $\sigma_{\text{HO}_2(\text{CRDS})}$  (19%),  $\sigma_{\text{HO}_2(\text{FAGE})}$  was used in the intercomparison of the CRDS and FAGE measurements (Sect. 3.5.2).

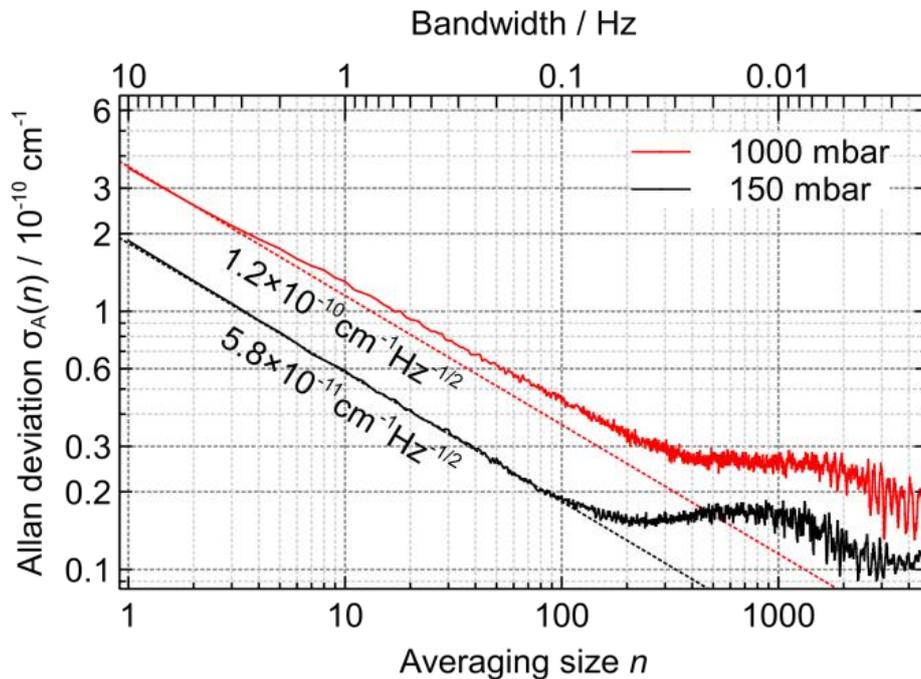

**Figure 6:** An example of a temporal decay of the  $\text{HO}_2$  absorption coefficient at 1506.43 nm from CRDS data (black circles) along with the FAGE signal scaled to overlap the CRDS data (see text for details). The traces were recorded at 295 K and with a 1000 mbar mixture of  $\text{N}_2:\text{O}_2 = 4:1$ ;  $[\text{Cl}_2]_0 \sim 1.7 \times 10^{14} \text{ molecule cm}^{-3}$  and  $[\text{CH}_3\text{OH}]_0 \sim 2.0 \times 10^{14} \text{ molecule cm}^{-3}$ . The fit of Eq. (9) to the CRDS data (green line) gave  $\sigma_{\text{HO}_2} = (3.59 \pm 0.52) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  while the fit of Eq. (9) to the scaled FAGE data (blue line) resulted in  $\sigma_{\text{HO}_2} = (3.54 \pm 0.05) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$ . The error limits are statistical errors at the  $1\sigma$  level.

### 3.4 Determination of the CRDS detection limits

In order to quantify the sensitivity of the CRDS spectrometer the chamber was filled with synthetic air at 150 mbar and 1000 mbar, respectively and single ring-down events were continuously acquired at 1506.43 nm for 1.0 – 1.5 hour. As the CRDS noise increased slightly when the fans were turned on, separate measurements were performed where the fans were maintained on and off, respectively. Fig. S4a in the supplementary information shows such separate measurements of the ring-down time at 1506.43 nm with the fans on and off, respectively as an example. The noise properties of the spectrometer can be characterized with an Allan deviation plot (Werle et al., 1993). The Allan variance,  $\sigma_A^2(n)$ , is the mean two-sample variance of pairs of adjacent points in a data series (absorption coefficients in our case), where each point is an average of  $n$  individual measurements (ring-down events). The Allan deviation,  $\sigma_A(n)$ , is  $(1/\sqrt{2})$  times the root-mean-square value of the difference between adjacent points. As such, the Allan deviation plot (Fig. 7 and Fig. S4b in the supplementary information) gives an estimate of the error,  $\delta\alpha$ , between successively measured absorption coefficients for a given averaging size  $n$ . At 1000 mbar, the optimum CRDS sensitivity is achieved by averaging  $\sim 600$  ring-down events (requiring 60 s at an acquisition rate of 10 Hz), giving a minimum detectable absorption coefficient of  $\delta\alpha_{\min} = 2.6 \times 10^{-11} \text{ cm}^{-1}$ . For  $n$  up to 3, the behaviour of  $\sigma_A(n)$  is that of white noise with a bandwidth-normalized value of  $1.2 \times 10^{-10} \text{ cm}^{-1} \text{ Hz}^{-1/2}$ . For  $n$  up to 100, the effect of excess noise is measurable but small, and for  $n$  larger than 100 the discrepancy becomes significant. At 150 mbar, the best sensitivity of  $\delta\alpha_{\min} = 1.5 \times 10^{-11} \text{ cm}^{-1}$  is achieved after averaging  $\sim 250$  events (25 s). The behaviour of  $\sigma_A(n)$  is that of white noise for  $n$  up to 100, with a bandwidth-normalized value of  $5.8 \times 10^{-11} \text{ cm}^{-1} \text{ Hz}^{-1/2}$ .

For a signal-to-noise ratio ( $S/N$ ) of 2, the limits of detection for  $\text{HO}_2$ ,  $LOD_{\text{HO}_2} = (2\delta\alpha_{\min})/\sigma_{\text{HO}_2}$ , where  $\sigma_{\text{HO}_2}$  is the  $\text{HO}_2$  cross section at 1506.43 nm the values shown in Table 1 were obtained.

**Figure 7:** Allan deviation plot of the absorption coefficient at 1506.43 nm in the absence of  $\text{HO}_2$  against the number of ring-down events averaged,  $n$ . For  $S/N = 2$  the minimum detectable absorption coefficient for a single ring-down measurement is:  $1.9 \times 10^{-10} \text{ cm}^{-1}$  at 150 mbar, which is reduced to  $1.5 \times 10^{-11} \text{ cm}^{-1}$  after averaging 250 ring-down time constants,  $\tau_0$  (requiring 25 s at an acquisition rate of 10 Hz) and  $3.6 \times 10^{-10} \text{ cm}^{-1}$  at 1000 mbar, which decreases to  $2.7 \times 10^{-11} \text{ cm}^{-1}$  after  $n = 600$  (requiring 60 s at an acquisition rate of 10 Hz).

Table 1. CRDS detection limits for HO<sub>2</sub> computed at 150 and 1000 mbar for single ring-down measurements ( $\Delta t = 0.1$  s), the optimum averaging time,  $\Delta t_{\text{opt}}$ , 25 s at 150 mbar and 60 s at 1000 mbar and two other averaging times:  $\Delta t = 3$  s and  $\Delta t = 30$  s.

$p_{\text{HIRAC}} / \text{mbar}$	$\sigma_{\text{HO}_2} \times 10^{20} / \text{cm}^2 \text{ molecule}^{-1}$	$LOD_{\text{HO}_2} \times 10^8 / \text{molecule cm}^{-3}$			
		$\Delta t = 0.1$ s	$\Delta t = 3$ s	$\Delta t = 30$ s	$\Delta t_{\text{opt}}$
150	$12.5 \pm 1.9^a$	30.4	5.6	2.7	2.4
	$10.2 \pm 1.8^b$	37.3	6.8	3.3	2.9

<sup>a</sup> determined using the line strengths of the HO<sub>2</sub> transitions contributing to the absorption at 1506.43 nm (Thiebaud et al., 2007) and the pressure broadening coefficients (Ibrahim et al., 2007) (Section 3.2)

<sup>b</sup> determined using the kinetics of the HO<sub>2</sub> second-order decays (Section 3.3)

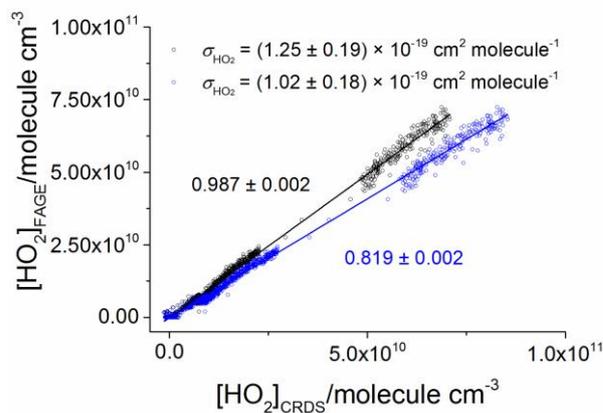

### 3.5 Intercomparison of CRDS and FAGE HO<sub>2</sub> measurements

#### 3.5.1 150 mbar measurements

HO<sub>2</sub> was generated from photolysis of mixtures of Cl<sub>2</sub>/CH<sub>3</sub>OH/O<sub>2</sub> over a range of concentrations,  $\sim 6\text{--}750 \times 10^8 \text{ molecule cm}^{-3}$  at 150 mbar and  $\sim 4\text{--}100 \times 10^9 \text{ molecule cm}^{-3}$  at 1000 mbar. The comparison involved both periods with lamps on where [HO<sub>2</sub>] was changing slowly and also where the lamps were turned off and the decay of HO<sub>2</sub> was followed. FAGE signals were converted into [HO<sub>2</sub>] using the calibration constant determined in Sect. 2.3.2 using the kinetic decay of HO<sub>2</sub> ( $C_{\text{HO}_2, 150 \text{ mbar}} = (2.6 \pm 0.5) \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$ ). CRDS absorptions were converted to concentrations based on either the cross-section derived from the study of the recombination kinetics in section 3.3.1 ( $\sigma_{\text{HO}_2, 150 \text{ mbar}} = (1.02 \pm 0.18) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$ ), or the value of the cross-section determined by application of pressure broadening to the spectral lines reported by Thiebaud et al. (2007) (Sect. 3.2;  $\sigma_{\text{HO}_2, 150 \text{ mbar}} = (1.25 \pm 0.19) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$ ). Figure 8a shows an example of a typical temporal profile of absolute HO<sub>2</sub> concentrations recorded over  $\sim 15$  minutes first with lamps on and then lamps switched off. The agreement between [HO<sub>2</sub>] determined by the FAGE method and the CRDS method with the Thiebaud et al. based cross-section is excellent (the difference is within 3%). Considering errors of approximately 20% in both the FAGE calibrations and absorption cross-section determined in the kinetic studies, then the FAGE determined HO<sub>2</sub> concentrations are also consistent with those from CRDS with our kinetically determined absorption cross-section. Figure 8b shows a correlation plot of the complete intercomparison dataset with the two different absorption cross-sections. The correlations are linear over the range of [HO<sub>2</sub>],  $\sim 6\text{--}750 \times 10^8 \text{ molecule cm}^{-3}$ , (average gradient =  $0.903 \pm 0.002$ ) with a very small negative intercept ( $(-1.0 \pm 0.5) \times 10^8 \text{ molecule cm}^{-3}$ ) which is insignificant compared to the typical HO<sub>2</sub> concentrations in this simulation chamber experiment.

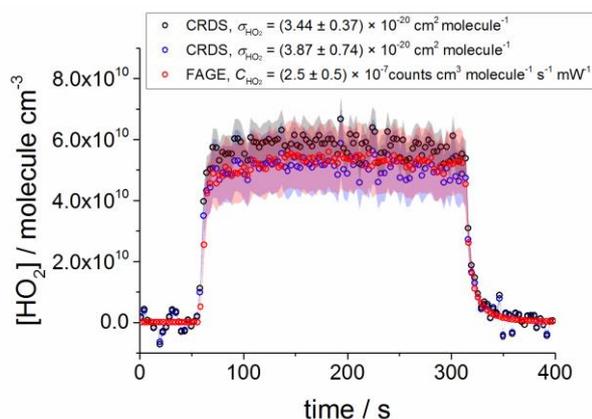

**Figure 8a.** Comparison HO<sub>2</sub> measurement at 150 mbar where the lamps were switched on at  $t \sim 150$  seconds for  $\sim 10$  minutes. HO<sub>2</sub> measured by FAGE ( $C_{150 \text{ mbar}} = 2.6 \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$ , red) is plotted with HO<sub>2</sub> measured by CRDS using  $\sigma_{\text{HO}_2} = 1.25 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  obtained (Sect. 3.2) by application of pressure broadening to the spectral lines found by Thiebaud et al. (2017) (black), and  $\sigma_{\text{HO}_2} = 1.02 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  determined using the kinetic decays of HO<sub>2</sub> in Sect. 3.3.1 (blue). Each datum point is an averaged value over 3 seconds.  $[\text{CH}_3\text{OH}] = 6.6 \times 10^{13} \text{ molecule cm}^{-3}$ ,  $[\text{Cl}_2] = 4.4 \times 10^{13} \text{ molecule cm}^{-3}$ .

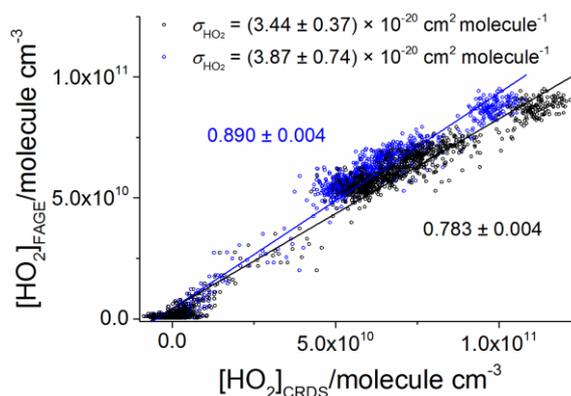

**Figure 8b.** Correlation plot at 150 mbar for data plotted in Fig. 8a.  $[\text{HO}_2]_{\text{CRDS}}$  was calculated using  $\sigma_{\text{HO}_2} = 1.25 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  determined in Sect. 3.2 (black) and  $\sigma_{\text{HO}_2} = 1.02 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  determined in Sect. 3.3.1 (blue). Linear **unweighted** fits of the data generated gradients of  $0.987 \pm 0.002$  and  $0.819 \pm 0.002$  respectively. Both lines intercept the y axis at  $(-1.0 \pm 0.5) \times 10^8 \text{ molecule cm}^{-3}$ .  $[\text{HO}_2]_{\text{FAGE}}$  was calculated using a sensitivity factor of  $2.6 \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$  from the HO<sub>2</sub> decay as discussed in Sect. 2.3.2. Each datum point is an averaged value over 3 seconds.

### 3.5.2 1000 mbar measurements

Figures 9a and b show the equivalent comparisons for data recorded at 1000 mbar. Once again two values for the CRDS derived concentrations are given, firstly based on the pressure broadened cross-section of Thiebaud et al. (2007) ( $\sigma_{\text{HO}_2} = (3.44 \pm 0.37) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$ ) and secondly from the experimentally determined cross-sections using the HO<sub>2</sub> decay (section 3.3.2,  $\sigma_{\text{HO}_2} = (3.89 \pm 0.74) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$ ). The data are more scattered reflecting the lower sensitivity of the CRDS technique at 1000 mbar, but once again the HO<sub>2</sub> concentrations determined by the two techniques (with either cross-section) are consistent within the  $\sim 20\%$  errors associated with the calibration of FAGE and the cross-section determinations (average gradient of the two correlation plots =  $0.836 \pm 0.004$ ).

**Figure 9a.** Comparison measurement at 1000 mbar where the lamps were left on for  $\sim 4$  minutes.  $\text{HO}_2$  measured by FAGE using the calibration factor obtained as shown in Sect. 2.3.1: the average of the value determined by the  $\text{H}_2\text{O}$  photolysis and the value obtained using the  $\text{HO}_2$  decays,  $C_{1000 \text{ mbar}} = 2.5 \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$ ; red circles, is plotted with  $\text{HO}_2$  measured by CRDS using  $\sigma_{\text{HO}_2} = 3.44 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  determined (Sect. 3.2) by application of pressure broadening to the spectral lines found by Thiebaud et al. (2017) (black circles), and  $\sigma_{\text{HO}_2} = 3.87 \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  determined using the kinetic decays of  $\text{HO}_2$  in Sect. 3.3.2 (blue circles). Each datum point is an averaged value over 3 seconds.  $[\text{CH}_3\text{OH}] \sim 1.65 \times 10^{15} \text{ molecule cm}^{-3}$ , and  $[\text{Cl}_2] \sim 1.10 \times 10^{14} \text{ molecule cm}^{-3}$ .

**Figure 9b.** Correlation plot at 1000 mbar for data in Fig. 9a.  $[\text{HO}_2]_{\text{CRDS}}$  was calculated using  $\sigma_{\text{HO}_2} = 3.44 \times 10^{-20} \text{ cm}^2$  determined as shown in Sect. 3.2 (black) and  $\sigma_{\text{HO}_2} = 3.87 \times 10^{-20} \text{ cm}^2$  determined as shown in Sect. 3.3.2 (blue). Linear **unweighted** fits of the data generated gradients of  $0.890 \pm 0.004$  and  $0.783 \pm 0.004$  respectively, and an intercept of  $(-4.3 \pm 0.3) \times 10^9$  and  $(-1.0 \pm 0.5) \times 10^8 \text{ molecule cm}^{-3}$  respectively.  $[\text{HO}_2]_{\text{FAGE}}$  was calculated using the sensitivity factor  $C_{1000 \text{ mbar}} = 2.5 \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$ , which is the average of the value determined by the  $\text{H}_2\text{O}$  photolysis and the mean value determined using the  $\text{HO}_2$  decays (Sect. 2.3.1). Each datum point is an averaged value over 3 seconds.

#### 4 Discussion

The  $\text{HO}_2$  near-IR absorption spectrum around 1506 nm recorded in this study using CRDS is in good agreement with previous work both in terms of the wavelength of the maximum absorption, and the cross-section at 150 mbar ( $\sigma_{\text{HO}_2, 150 \text{ mbar}}$ ), as determined here by kinetics measurements. The  $\sigma_{\text{HO}_2, 150 \text{ mbar}}$  from the kinetics studies  $(1.02 \pm 0.18) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  (Sect. 3.3.1) is within the error ranges of derived from two previous studies: (i)  $\sigma_{\text{HO}_2, 150 \text{ mbar}} = (1.25 \pm 0.19) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  computed using the 50 mbar He measurements of Thiebaud et al. (2007), where the line centres and strengths of the  $\text{HO}_2$  transitions at  $\sim 1506.43 \text{ nm}$  were extracted from the reported spectra and combined with the pressure broadening in air (Ibrahim et al., 2007) (Sect. 3.2) to give  $\sigma_{\text{HO}_2}$  at 150 mbar, and (ii)  $\sigma_{\text{HO}_2, 150 \text{ mbar}} = (1.29 \pm 0.23) \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  obtained by extrapolating the cross-sections determined by Tang et al. (2010) in the range of 27–133 mbar. Significant pressure broadening is observed such that the lower cross-section at 1000 mbar,  $\sigma_{\text{HO}_2, 1000 \text{ mbar}}$ , and hence reduced signal to noise, makes extraction of a precise  $\sigma_{\text{HO}_2}$  using the CRDS data from the recombination kinetics difficult. However, a comparison of the temporal profiles of the  $\text{HO}_2$  decays from CRDS and FAGE (e.g. Fig. 6) shows good agreement and the resulting absorption cross-section, an average from the analysis of 6 decays,  $\sigma_{\text{HO}_2} = (3.89 \pm 0.74) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$ , is in good agreement with the value of  $\sigma_{\text{HO}_2} = (3.44 \pm 0.37) \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  obtained by application of pressure broadening to the data of Thiebaud et al. (2007).

The good agreement (only  $\sim 10$ – $15$  % difference on average) between CRDS and FAGE for both the  $\text{HO}_2$  concentrations with the lamps on and their temporal dependence when the lamps were switched off, as exemplified in Figs. 6, 8 and 9 (see also Figs. S7 and S8 in the supplementary information), provides validation between the absolute and direct method of  $\text{HO}_2$  detection via CRDS and the FAGE technique which is an indirect method requiring calibration. The CRDS method requires a known  $\sigma_{\text{HO}_2}$  and this is non-trivial to obtain for a radical species, so there are systematic uncertainties of approximately 20% associated with CRDS measurements of  $\text{HO}_2$ . Whilst no significant concerns have been raised about either

the photolysis of water vapour at 185 nm in air as a method to generate HO<sub>2</sub> for calibration, or the indirect method of determining HO<sub>2</sub> by NO titration to OH (at least for the simple chemical environments described in this paper), this is the first direct, real time, quantitative intercomparison between CRDS and FAGE for HO<sub>2</sub> detection. The good agreement between the two techniques raises confidence for their application. Such a level of agreement provides evidence for there being no undetected systematic errors in either technique. Note that this work also supports the method used to measure HO<sub>2</sub> via the CIMS technique as CIMS also relies on a similar methodology, namely titration with NO to convert HO<sub>2</sub> to OH (Edwards et al., 2003).

Table 2 compares the *LOD* of the CRDS system described here with the *LOD* values reported in previous studies using the first overtone of the O-H stretch in near IR to detect HO<sub>2</sub> through different techniques: CRDS (Thiebaud et al., 2007; Thiebaud et al., 2008; Liu et al., 2008), noise-immune cavity-enhanced optical heterodyne molecular spectroscopy, NICE-OHMS (Bell et al., 2012) and wavelength modulation near IR spectroscopy, WM-NIR (Noell et al., 2010). The CRDS instrument used in this work allows for more sensitive measurements of HO<sub>2</sub> than in the above cited references. However, the instrument has insufficient sensitivity to detect ambient levels of HO<sub>2</sub>, where typical maximum concentrations are very dependent upon NO<sub>x</sub> and range from  $(0.5 - 10) \times 10^8$  molecule cm<sup>-3</sup> (Carlaw et al., 2001; Heard et al., 2004; Dusanter et al., 2009; Holland et al., 2003) and ideally a detection limit  $< 1 \times 10^7$  molecule cm<sup>-3</sup> is required. However, the sensitivity (*LOD* for [HO<sub>2</sub>] with 30 s averaging at 1000 mbar  $\sim 1.5 \times 10^9$  molecule cm<sup>-3</sup>) is more than adequate for chamber studies where in general [HO<sub>2</sub>]  $> 3 \times 10^{10}$  molecule cm<sup>-3</sup> can be generated and 30 second averaging should provide good temporal resolution as experiments typically take between 10 and 120 minutes (Malkin et al., 2010; Winiberg et al., 2016). It is stressed however that the *LOD* quoted here is in the absence of water vapour. No change in the *LOD* at 150 mbar in the presence of typical ambient concentrations of water ( $10^{17}$  molecule cm<sup>-3</sup> orders of magnitude) is expected at 150 mbar as there is little overlap of the water absorption lines with the HO<sub>2</sub> absorption at 1506.43 nm at this pressure. However, in the presence of [H<sub>2</sub>O]  $\sim 10^{17}$  molecule cm<sup>-3</sup> the CRDS sensitivity at 1000 mbar is expected to decrease markedly relative to the sensitivity in dry air found in this work due to the pressure broadening of the H<sub>2</sub>O spectral lines resulting in a significant H<sub>2</sub>O absorption at 1506.43 nm in the background of the HO<sub>2</sub> measurements.

Table 2. Comparison of the detection limits (*LOD*) for HO<sub>2</sub> obtained in this work with previously reported *LOD* (extrapolated to 30 s integration time, 0.033 Hz detection bandwidth) obtained by detecting HO<sub>2</sub> in near IR via the first vibrational overtone of the O-H stretch

<i>LOD</i> / molecule cm <sup>-3</sup>	Wavelength / nm	Pressure / mbar	Bath gas	Technique	Reference

<sup>a</sup> Cavity ring-down spectroscopy (CRDS); Calculated for  $\sigma_{\text{HO}_2} = 2.7 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$ ;  $\alpha_{\text{min}} = 1.2 \times 10^{-9} \text{ cm}^{-1} \text{ Hz}^{-1/2}$

<sup>b</sup> Calculated for  $\sigma_{\text{HO}_2} = 3.4 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  and  $\alpha_{\text{min}} = 1.1 \times 10^{-9} \text{ cm}^{-1} \text{ Hz}^{-1/2}$

<sup>c</sup> *LOD* computed by using the noise level of the HO<sub>2</sub> spectrum baseline and corresponded to  $\alpha_{\text{min}} \sim 3 \times 10^{-8} \text{ cm}^{-1}$  for HO<sub>2</sub> generated in dielectric barrier discharge plasma; bandwidth unknown

<sup>d</sup> Noise-immune cavity-enhanced optical heterodyne molecular spectroscopy (NICE-OHMS);  $\sigma_{\text{HO}_2, 1509.82} = 9.7 \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  and  $\sigma_{\text{HO}_2, 1509.76} = 1.3 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$ ; *LOD* calculated for a sensitivity of  $\alpha_{\text{HO}_2} = 5.7 \times 10^{-9} \text{ cm}^{-1} \text{ Hz}^{-1/2}$

<sup>e</sup> Wavelength modulation near IR (WM-NIR) spectroscopy; *LOD* given as  $1 \times 10^{11} \text{ cm}^{-3} \text{ Hz}^{-1/2}$ ; typical concentrations:  $(3 - 15) \times 10^{16} \text{ molecule cm}^{-3}$  He,  $(5 - 20) \times 10^{17} \text{ molecule cm}^{-3}$  O<sub>2</sub> and  $(0-1) \times 10^{18} \text{ molecule cm}^{-3}$  N<sub>2</sub>

<sup>f</sup> Average of the two *LOD* shown in Table 1 (computed for  $\sigma_{\text{HO}_2} = 1.25 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$  and  $\sigma_{\text{HO}_2} = 1.02 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$ );  $S/N = 2$

<sup>g</sup> Average of the two *LOD* shown in Table 1 (computed for  $\sigma_{\text{HO}_2} = 3.44 \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$  and  $\sigma_{\text{HO}_2} = 3.87 \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$ );  $S/N = 2$

The CRDS sensitivity could be further optimised by setting up the CRDS along HIRAC to increase the cavity length to 2.0 m (from the present length of 1.4 m). Measurements of fast kinetic decays of HO<sub>2</sub> and averaging of ring-down events where HO<sub>2</sub> is in steady-state would benefit from an increase of the frequency of the ring-down events. No improvement of the sensitivity is expected by changing the wavelength of the measurements to another value in near IR as this work has been already performed at the wavelength of the most important HO<sub>2</sub> absorption feature (1506.43 nm) in the range of  $\sim 1493 - 1514 \text{ nm}$  (vacuum wavelength corresponding to  $6604 - 6696 \text{ cm}^{-1}$ ) where the first overtone of the O-H stretch has been observed (Thiebaud et al., 2007; DeSain et al., 2003). Even though the mid IR range provides stronger HO<sub>2</sub> absorption cross sections (Richard et al., 2012), the near IR region has been chosen for this study as it offers advantages such as improved performance of the detectors and optical components, which are also available at a lower cost.

In terms of practical operation, both the FAGE and CRDS methods require trained operatives and constant monitoring of conditions to ensure optimum performance; neither technique could be considered as a ‘turn-key’ process. The CRDS system does have a significant advantage in cost with the current apparatus being assembled for a cost of  $\sim \text{£} 9 \text{ k}$ .

## 5 Conclusions

The Fluorescence Assay by Gas Expansion (FAGE) technique is the most commonly used method for the measurement of HO<sub>2</sub> in the atmosphere by conversion of HO<sub>2</sub> to OH by reaction with added NO followed by OH on-resonance LIF at 308 nm. However, FAGE is not an absolute method and hence requires calibration. In this work an intercomparison is performed between the FAGE technique and the absolute Cavity Ring-Down Spectroscopy (CRDS) method within the Leeds HIRAC atmospheric simulation chamber. FAGE was conducted by sampling through a pinhole at  $\sim 0.2 \text{ m}$  from the chamber wall (1.2 m internal diameter), while CRDS probed HO<sub>2</sub> over the entire width of the chamber, using the excitation of the first O-H overtone at 1506.43 nm. The HO<sub>2</sub> radical was generated from photolysis of mixtures of Cl<sub>2</sub>/CH<sub>3</sub>OH/O<sub>2</sub> at room temperature and two total pressures (150 mbar and 1000 mbar of synthetic air) and was monitored simultaneously using the two techniques.

At 1000 mbar FAGE was calibrated using two different methods: the conventional calibration method consisting in the 185 nm photolysis of water vapour in synthetic air and the kinetic decay of the fluorescence signal method. The two methods were in agreement to within 8%; the average of the calibration factors obtained by the two methods was

$\bar{C}_{\text{HO}_2, 1000 \text{ mbar}} = (2.5 \pm 0.5) \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$ , which corresponds to a limit of detection (*LOD*) of  $1.6 \times 10^6 \text{ molecule cm}^{-3}$  for a signal-to-noise (*S/N*) ratio of 2 and an averaging period of 30 s. At 150 mbar the kinetic method was used for FAGE calibration, which yielded  $C_{\text{HO}_2} = (2.6 \pm 0.5) \times 10^{-7} \text{ counts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ mW}^{-1}$  and, hence a *LOD* similar to that obtained at 1000 mbar. The HO<sub>2</sub> absorption cross section at 1506.43 nm,  $\sigma_{\text{HO}_2}$ , at 150 and 1000 mbar was determined using two independent methods: from the 50 mbar He measurements of Thiebaud et al. (2007), where the line centres and strengths of the HO<sub>2</sub> transitions at  $\sim 1506.43 \text{ nm}$  were extracted from the reported spectra and combined with the pressure broadening in air (Ibrahim et al., 2007), and from the kinetics of the second-order HO<sub>2</sub> decays. At each operating pressure the values of  $\sigma_{\text{HO}_2}$  obtained by the two methods agree with each other (within  $\sim 12\%$  agreement at 1000 mbar and within  $\sim 20\%$  agreement at 150 mbar). For a time resolution of 30 s the computed CRDS sensitivity using the Allan deviation plots and the average  $\sigma_{\text{HO}_2}$  at each pressure are:  $3.0 \times 10^8$  at 150 mbar and  $1.5 \times 10^9 \text{ molecule cm}^{-3}$  at 1000 mbar.

The comparison was performed for both periods where [HO<sub>2</sub>] was decreasing slowly for 5–10 min and periods where the lamps were shortly turned on and then off to generate a series of HO<sub>2</sub> decays to encompass a wide range of [HO<sub>2</sub>]:  $\sim 6\text{--}750 \times 10^8 \text{ molecule cm}^{-3}$  at 150 mbar and  $\sim 4\text{--}100 \times 10^9 \text{ molecule cm}^{-3}$  at 1000 mbar. The correlation plots at both pressures show a good agreement between [HO<sub>2</sub>] measured using the indirect FAGE method and the direct CRDS method: a gradient of  $0.987 \pm 0.002$  when  $\sigma_{\text{HO}_2}$  determined by application of pressure broadening to the reported spectral lines (Thiebaud et al., 2007) was used at 150 mbar and average gradients (of the results obtained using the two  $\sigma_{\text{HO}_2}$  values at each pressure) of  $0.903 \pm 0.002$  at 150 mbar and of  $0.836 \pm 0.004$  at 1000 mbar. This intercomparison study provides a validation for the FAGE method and supports the use of the method employing CIMS for HO<sub>2</sub> measurements, which also relies on the conversion of HO<sub>2</sub> to OH by titration with NO (Edwards et al., 2003).
