We would like to thank Referee #1 for the insightful comments. We revised the manuscript accordingly. We present our responses and changes below. The reviewer’s comments and suggestions are in *italic*. Authors’ responses are in **bold**.

**Response to Referee #1:**

*This manuscript summarizes the sensitivity of OMI NO₂ trend to several factors such as a baseline trend (over the ocean), surface albedo, and lightning filter. I found the information in the manuscript is useful. The paper is well organized and presentations are neat. But I think that general conclusions (or contents in the abstract) are misleading and some important analyses are missing. I suggest to revise the manuscript before final publication based on the comments below.*

This research focuses on improving OMI NO₂ retrieval (instead of sensitivities) in trend analysis by removing the ocean trend (due to increasing stripes), using MODerate-resolution Imaging Spectroradiometer (MODIS) albedo in deriving air mass factors (AMFs), and applying the lightning flash filter. The three corrections are necessary for NO₂ trend analysis using OMI NO₂ retrieval.

*First, I do not agree with the authors in the abstract line 14-15 (‘‘how to improve OMI NO2 retrievals for more reliable trend analysis’’) and line 23-25 (‘‘we recommend future studies to apply these procedures to ensure the quality of satellite based NO2 trend analysis, especially in regions without reliable long-term in situ NO2 measurements’’). I think the agreement between the trends in surface monitored data (AQS) and those in standard OMI (Table 1) is already good, considering uncertainties in the satellite retrievals and the spatial coverage of the surface monitors. The authors need to clarify the spatial resolution of the OMI data (used in the trend analysis) and the spatial extent (or representativeness) of the ground-based observations.*

*We added in the abstract “However, the current OMI tropospheric NO₂ retrievals are not designed for analyzing multi-year tropospheric NO₂ trends.” It is not surprising that satellite data need to be reprocessed in trend analysis, which is true for all observation-based trend studies.*

The reason Table 1 results may be conceived to be “already good” (at for coincident data) is because we showed only annual trends. It did show that for all data, the effects of our recommended data processing are > a factor of 2 for West, Midwest, and South (comparing the OMI column with and without the lightning filter). We now emphasized this point in the abstract and conclusions.

*We further make the points that (1) processed OMI data show smaller trends (Figure 8) and (2) using surface data alone will have a tendency to overestimate NO₂ trends (Figure 9). Lastly, Figs. 4-7 show that on a seasonal basis, the effects of the data processing we recommended can be much larger than the annual mean changes of Table 1.*

To deal with the surface measurement representativeness, we only compare to regional trends from surface observations, which are much more statistically representative. Previous studies did the same. As discussed above, we show the effects of site locations on the trend analysis in Fig. 10 (and Table 1). This point has not been emphasized previously and needs to be accounted for in future studies.

*It is exciting to see better agreement between the trends from AQS and the final OMI (lightning filter) in Table 1. But I am not sure that these two should agree exactly.*

As our research focuses on the regional relative trend difference, we expect that the surface NO₂ trends and NO₂ VCD trends should be very close (They are both affected by chemical non-linearity and may show trends different from emission trends). We stated this in Section 3.1, “The NO₂ relative trends from
both datasets are expected to be close on a regional basis where surface emissions of NOx dominate the observed surface concentrations and tropospheric VCDs of NO2. As the reviewer already pointed out that the trends between surface and OMI coincident data are already in reasonably good agreement for annual trends, which is a reflection of this reasoning. We showed in this paper what improvements can be made further, the physical reasons, and the implications for understanding regional NO2 trends.

Figure 4 shows that the effects of different OMI retrievals are not clear except DJF in Midwest and Northeast. If summertime or typical ozone season satellite data are used for the trend study, it is not worth trying different retrievals or corrections suggested in this study.

We do not quite understand this comment. Figure 4 only shows the effects of adding ocean and MODIS corrections only, which can be quite large for some regions and some seasons already. These effects obviously need to be understood. Figure 7 shows the effects of adding lightning filter to the previous two corrections. We think that it shows clearly that all three corrections are necessary for doing trend analysis.

In general, the manuscript reports the impact of uncertainties of satellite tropospheric NO2 retrievals on the trend analysis. This is a sensitivity test study that provides useful information and can be a good reference to summarize the uncertainties in the OMI NO2 based trend analysis. However, I do not think it has broad and substantial impacts to change or shape future research.

One thing missing is a validation of a priori model NO2 profile or near surface NO2. According to this study, NO2 columns (potentially NOx emissions) decrease by ~40% for 10 years. How does satellite NO2 column retrieval change if a priori profiles come from the model results incorporating this reduced NOx emission (e.g., 40% reduction to 70% reduction considering a potential error in the emission).

We need to clarify that this work is not a sensitivity test study but proposing three necessary corrections to satellite retrievals used in trend analysis. Due to the chemical non-linearity (Gu et al., 2016), the NO2 VCD trend differs from NOx emission trend. As NO2 columns decrease by ~40%, the NOx emissions decrease by less than ~40%.

Lamsal et al. (2015) reported that using 2005 emission profile results in an underestimation of generally less than 2% of overall 2005-2010 NO2 reduction in polluted regions and that the trend is less sensitive to the vertical profile assumption in highly polluted areas (Section 2.2.2 and Figure 3, Lamsal et al., 2015). This is about an underestimation of about 0.3% yr\(^{-1}\), which could be used to explain the residual discrepancy (0.0-0.4% yr\(^{-1}\)) between OMI-based and in situ NO2 trends.

The proper way to estimate the effects of NOx emissions on NO2 VCDs is to perform proper inverse modeling of NOx emissions (e.g., Gu et al., 2014). However, the satellite data still need to be processed such that factors we discussed in this work do not introduce artifacts in tropospheric NO2 column trends. In the inverse modeling by Gu et al. (2014), the effects of AMF changes on inverse modeling will be accounted for, which we believe is the proper method for deriving NOx emission trends. That is to say that all proper inverse modeling studies of NOx emission trend should include AMF calculation that is derived from the a posteriori (not a priori) NOx emissions and it is the appropriate method of quantify the relative small effects. We added this point to the last sentence in the conclusions.

We revised the sentence in Section 2.3, as follows:

“The yearly variations of meteorology and anthropogenic emission changes have little impact in polluted areas on trend analysis results using OMI data (Lamsal et al., 2015).”
We revised one sentence in Section 3.1.3, as follows:

“The remaining seasonal difference of the trends reflects in part the nonlinear photochemistry (Gu et al., 2013) and the effects of NOx emission changes on NO2 retrievals (Lamsal et al., 2015).”

Final comment is to elaborate the correction of NO2 measurements by molybdenum converter. The plot in supplementary material (Figure S1) can include more details for the 7 sites. The diurnal variation in each season (if not month) and standard deviation in the plot will be helpful to characterize the ratios between surface NO2 concentrations of chemiluminescence to photolytic instruments. The plots for each site (7 sites) will be useful for readers.

The diurnal variation of the ratio is irrelevant to this research, as OMI overpasses only at around 13:30 local time. Due to the lack of photolytic instruments in each site, we used the averaged ratio between chemiluminescent to photolytic NO2 measurements in 7 available sites. The individual plots for these 7 sites can be misleading due to data availability. As we stated in Section 2.1, this correction will affect absolute trends but not relative trends, which are what we analyzed in this study. We added the 95th percentile confidence intervals to Figure S1.

Figure S1. The ratios between surface NO2 concentrations of chemiluminescence to photolytic instruments. The ratios are calculated for each month from 7 sites with coincident photolytic measurements. The shaded area shows the 95th percentile confidence intervals.
Reconciling the differences between OMI-based and EPA AQS in situ NO$_2$ trends

Abstract. With the improved spatial resolution than earlier instruments and more than ten years of service, tropospheric NO$_2$ retrievals from the Ozone Monitoring Instrument (OMI) have led to many influential studies on the relationships between socioeconomic activities and NOx emissions. However, the current OMI tropospheric NO$_2$ retrievals are not designed for analyzing multi-year tropospheric NO$_2$ trends. This study focuses on how to improve OMI NO$_2$ retrievals for more reliable trend analysis. We retrieve OMI tropospheric NO$_2$ vertical column densities (VCDs) and obtain the NO$_2$ seasonal trends over the United States, which are compared with coincident in situ surface NO$_2$ measurements from the Air Quality System (AQS) network. The Mann-Kendall method with the Sen’s slope estimator is applied to derive the NO$_2$ seasonal and annual trends for four regions at coincident sites during 2005-2014. The OMI-based NO$_2$ seasonal relative trends are generally biased high compared to the in situ trends by up to 3.7% yr$^{-1}$, except for the underestimation in the Midwest and Northeast during Dec-Jan-Feb (DJF). We improve the OMI retrievals for trend analysis by removing the ocean trend, using the MODerate-resolution Imaging Spectroradiometer (MODIS) albedo data in air mass factor (AMF) calculation, and applying a lightning flash filter to exclude lightning affected OMI NO$_2$ retrievals. These improvements result in close agreement (within 0.3% yr$^{-1}$) between in situ and OMI-based NO$_2$ regional annual relative trends. Thus, the derived OMI-based annual regional NO$_2$ trends change by a factor of > 2 for the South, the Midwest, and the West and seasonal changes can be even larger. We recommend future studies to apply these procedures to ensure the quality of satellite-based NO$_2$ trend analysis, especially in regions without reliable long-term in situ NO$_2$ measurements. We derive optimized OMI-based NO$_2$ regional annual relative trends using all available data for the West (-2.0%±0.3 yr$^{-1}$), the Midwest (-1.8%±0.4 yr$^{-1}$), the Northeast (-3.1%±0.5 yr$^{-1}$), and the South (-0.9%±0.3 yr$^{-1}$). The OMI-based annual mean trend over the contiguous United States is -1.5%±0.2 yr$^{-1}$. It is a factor of 2 lower than that of the AQS in situ data (-3.9%±0.4 yr$^{-1}$); the difference is mainly due to the fact that the locations of AQS sites are concentrated in urban and suburban regions.
1 Introduction

Nitrogen dioxide (NO$_2$) is an air pollutant. At high concentrations, it aggravates respiratory diseases and can lead to acid rain formation (e.g., Lamsal et al., 2015). It is also a key player to produce another pollutant, ozone (O$_3$), through photochemical reactions in the presence of Volatile Organic Compounds (VOCs) under sunlight. Tropospheric NO$_2$ is emitted both anthropogenically and naturally (e.g., Gu et al., 2016). Anthropogenic fossil fuel combustions and biomass burnings emit mostly nitrogen monoxide (NO) under high temperature, which is later oxidized by O$_3$ into NO$_2$. Major natural NO$_2$ sources include lightning and soils.

Surface NO$_2$ concentrations are regulated by the U.S. Environmental Protection Agency (EPA) through the National Ambient Air Quality Standards (NAAQS). NO$_2$ is measured routinely at the EPA Air Quality System (AQS) sites (Demerjian, 2000). Although the AQS network continually provides valuable hourly NO$_2$ measurements, AQS sites are mostly located in urban and suburban regions, leaving large regions of rural areas unmonitored. Satellite data provide a better spatial coverage than the in situ measurements.

Several satellites were launched to monitor tropospheric NO$_2$ vertical column densities (VCDs), such as the SCanning Imaging Absorption spectroMeter for Atmospheric CHartographY (SCIAMACHY), the Global Ozone Monitoring Experiment–2 (GOME-2), and the Ozone Monitoring Instrument (OMI). For trend analysis, the tropospheric NO$_2$ products from OMI surpass the others for a relatively high spatial resolution and over one decade of continuous operation (Boersma et al., 2004; Boersma et al., 2011). Thus, OMI NO$_2$ retrievals are widely applied in NO$_2$ and NOx emission trend studies (e.g., Lin et al., 2010, 2011; Castellanos et al., 2012; Russell et al., 2012; Gu et al., 2013; Lamsal et al., 2015; Lu et al., 2015; Tong et al., 2015; Cui et al., 2016; Duncan et al., 2016; de Foy et al., 2016a, 2016b; Krotkov et al., 2016; Liu et al., 2017). Tong et al. (2015) reported that the reduction rates calculated from OMI NO$_2$ VCDs and AQS surface NO$_2$ data at eight cities were -35% and -38% from 2005 to 2012, respectively. Lamsal et al. (2015) also found the divergence between the annual trends inferred from the two datasets, i.e. -4.8% yr$^{-1}$ vs -3.7% yr$^{-1}$ during 2005-2008, and -1.2% yr$^{-1}$ vs -2.1% yr$^{-1}$ during 2010-2013. There are several potential factors attributing to the discrepancies between trends from satellite and ground-based measurements: interferences by the oxidation products of NOx from the chemiluminescent instruments (Lamsal et al., 2008, 2014, 2015), the differences of sampling time between OMI (~13:30 local time) and AQS (hourly) measurements (Tong et al., 2015), a high sensitivity of NO$_2$ VCDs to high-altitude NO$_2$ in contrast to the high sensitivity of surface NO$_2$ concentrations to surface NOx emissions (Duncan et al., 2013; Lamsal et al., 2015), spatial representativeness of satellite pixels (Lamsal et al., 2015), and high uncertainties of satellite retrievals in clean regions (Lamsal et al., 2015).

To understand how various factors and the retrieval procedure affect the resulting OMI derived trends and their differences from those derived from the surface AQS measurements, we utilize a regional 3-D chemistry transport model (CTM), a radiative transfer model (RTM), and the Mann-Kendall method (Mann, 1945; Kendall, 1948) to calculate OMI-based NO$_2$ seasonal relative trends during Dec-Jan-Feb (DJF), Mar-Apr-May (MAM), Jun-Jul-Aug (JJA), and Sept-Oct-Nov (SON) (Section 2). To reconcile with the AQS
based regional NO$_2$ trends, we find that three procedures are essential to ensure the quality of trend analysis using OMI tropospheric NO$_2$ VCDs, including the ocean trend removal, the MODerate-resolution Imaging Spectroradiometer (MODIS) albedo update in calculating the air mass factors (AMFs), and the lightning filter (Section 3.1). With these procedures implemented, the differences between OMI-based and AQS in situ annual relative trends are within 0.3% yr$^{-1}$ of coincident measurements for all the four regions. Finally, we estimate the OMI-based annual relative trends across the nation in Section 3.2. Conclusions are given in Section 4.

2 Methods

2.1 EPA AQS surface NO$_2$ measurements

The in situ surface NO$_2$ measurements from the U.S. EPA AQS network are used in this research. Sites with a continuous measurement gap of more than 50 days are removed and the observations of 140 remaining cites are used (Fig. 1). The AQS chemiluminescent analyzers are equipped with molybdenum converters to measure ambient NO$_2$ concentrations. These analyzers are known to have high biases, since the converters are not NO$_2$ specific and they measure some fractions of peroxyacetyl nitrate, nitric acid and organic nitrates (Demerjian, 2000; Lamsal et al., 2008). In addition to chemiluminescent analyzers, several NO$_2$ specific photolytic instruments were deployed since 2013. By utilizing the data from both chemiluminescent and photolytic measurements at coincident sites during the overpassing time of OMI, we calculate the observed NO$_2$ concentration ratio between both measurements in Fig. S1 in the Supplement. The ratio peaks at 2.3 in June and decreases to 1.3 in November, indicating that the chemiluminescent analyzers overestimate by 27%–132% than photolytic instruments. This finding is in agreement with Lamsal et al. (2008). We correct the chemiluminescent NO$_2$ data by the observed ratio assuming that the inter-annual change is small. This correction may contribute to the differences between in situ and OMI based absolute NO$_2$ trends but do not significantly affect the relative trends (since the correction is canceled out in computing relative trends). In this study, we only examine the relative trends and therefore the analysis results are not affected by the uncertainties in the in situ NO$_2$ measurement corrections.

2.2 REAM model

We use a 3-D Regional chEmical trAnsport Model (REAM) in the simulation of NO$_2$ profiles. REAM has widely been used in atmospheric NO$_2$ studies, including vertical transport (Choi et al., 2005; Zhao et al., 2009a; Zhang et al., 2016a), emission inversions (Zhao et al., 2009b; Yang et al., 2011; Gu et al., 2013, 2014, 2016), and regional and seasonal variations (Choi et al., 2008a, 2008b). The model has a horizontal resolution of 36 km with 30 vertical layers in the troposphere, 5 vertical layers in the stratosphere, and a model top of 10 hpa. In this study, the domain of REAM is about 400 km larger on each side than the contiguous United States (CONUS). Meteorology inputs driving transport process are simulated by the Weather Research and
Forecasting model (WRF) assimilations constrained by National Centers for Environmental Prediction Climate Forecast System Reanalysis (NCEP CFSR, Saha et al., 2010) 6-hourly products. The KF-eta scheme is used for sub-grid convective transport in WRF (Kain and Fritsch, 1993). We run the WRF model with the same resolution as in REAM but with a domain 10 grids larger on each side than that of REAM. REAM updates most of the meteorology inputs every 30 minutes while those related to convective transport and lightning parameterization are updated every 5 minutes. The chemistry mechanism expands that of a global CTM GEOS-Chem (V9-02) with aromatics chemistry (Bey et al., 2001; Liu et al., 2010, 2012a, 2012b; Zhang et al., 2017). For consistency, the GEOS-Chem (V9-02) simulation with 2° × 2.5° resolution is used to generate initial and boundary conditions for chemical tracers.

Anthropogenic emissions of NOx and other chemical species are from the U.S. National Emission Inventory 2008 prepared using the Sparse Matrix Operator Kernel Emission (SMOKE) model. Biogenic emissions are simulated online using the Model of Emissions of Gases and Aerosols from Nature (MEGAN) algorithm (v2.1, Guenther et al., 2012). We parameterize lightning emitted NOx as a function of convective mass flux and Convective Available Potential Energy (CAPE) (Choi et al., 2005). NOx production per flash is set to 250 moles NO per flash, and the emissions are distributed vertically following the C-shaped profiles by Pickering et al. (1998). For recent model evaluations of REAM with observations, we refer readers to Zhang et al. (2016a, 2016b), Cheng et al. (2017), and Zhang et al. (2017).

2.3 OMI-based NO2 VCDs

We retrieve the tropospheric NO2 VCDs using the tropospheric slant column densities (SCDs) from the Royal Dutch Meteorological Institute (KNMI) Dutch OMI NO2 product (DOMINO v2, Boersma et al., 2011). OMI onboard the Aura satellite was launched in July 2004 and is still active. OMI overpasses the equator at about 13:30 Local Time (LT) and obtains global coverage with a 2600 km viewing swath spanning 60 rows. It has a ground level spatial resolution up to 13 km x 24 km (at nadir). The spatial extent of the OMI pixels will not affect our analysis as we focus on regional trend analysis. SCDs are retrieved by matching a modeled spectrum to an observed top-of-atmosphere reflectance with the Differential Optical Absorption Spectroscopy (DOAS) technique within a fitting window of 405-465nm. The stratospheric portion of SCDs are estimated and subsequently removed with a global CTM TM4 with stratospheric ozone assimilation (Dirksen et al., 2011). Deriving tropospheric VCDs from the remaining tropospheric SCDs requires the calculation of AMFs. Being an optically thin gas, tropospheric AMF for NO2 can be calculated from AMF for each vertical layer ($AMF_i$) weighted by NO2 partial VCDs at the corresponding layer ($\chi_i$) (Boersma et al., 2004), as shown in equation (1).

$$\text{tropospheric AMF} = \frac{\text{tropospheric SCD}}{\text{tropospheric VCD}} = \int \frac{AMF_i \chi_i dl}{\int \chi_i dl}$$

As the vertical distribution of NO2 is usually unknown, we typically substitute $\chi_i$ by an a priori profile ($\chi_{a priori}$) from a CTM. $AMF_i$ is the sensitivity of NO2 SCD to VCD at a given altitude (Eskes and Boersma, 2003), and is computed using the Double Adding KNMI (DAK) RTM (Lorente et al., 2017). As a result, the
retrieved tropospheric NO\textsubscript{2} VCD computation depends on the a priori NO\textsubscript{2} vertical profile, the surface reflectance, the surface pressure, the temperature profile, and the viewing geometry (Boersma et al., 2011). Previous studies have addressed the sources of uncertainties in NO\textsubscript{2} retrievals, including surface reflectance resolutions (Russell et al., 2011; Lin et al., 2014), lightning NOx (Choi et al., 2005a; Martin et al., 2007; Bucsela et al., 2010), a priori CTM uncertainties (Russell et al., 2011; Heckel et al., 2011; Lin et al., 2012; Laughner et al., 2016), surface pressure and reflectance anisotropy in rugged terrain (Zhou et al., 2009), cloud and aerosol radiance (Lin et al., 2014, 2015), and boundary layer dynamics (Zhang et al., 2016a). The We find that the NO\textsubscript{2} VCD trend analysis is particularly sensitive to the first two factors and we will discuss these in the following sections.

AMFs are derived using the pre-computed altitude-dependent AMF lookup table, which is generated by the DAK RTM. We use the NO\textsubscript{2} profiles from REAM, temperature and pressure from CSFR, viewing geometry and cloud information from DOMINO v2 product. We use the REAM results of 2010 to avoid the uncertainty introduced by yearly variation of NO\textsubscript{2} profiles. The yearly variations of meteorology and anthropogenic emission changes have little impact in polluted areas on trend analysis results using OMI data (Lamsal et al., 2015). We use the surface reflectance from DOMINO v2 product as default (Kleipool et al., 2008), and update it using a surface reflectance product with a higher temporal resolution (Section 2.3.2). The derived tropospheric NO\textsubscript{2} VCD relative trends with default surface reflectance are referred as “Standard”.

**2.3.1 Ocean trend removal**

For trend and other analyses of OMI tropospheric VCDs, the data of anomalous pixels must be removed. The row anomaly initially occurred in June 2007 and subsequently in later years affected rows 26-40 (Schenkeveld et al., 2017). Additional anomalies can be found in some years in rows 41-55. For trend analysis from 2005-2014, we exclude rows 26-55, consistent with our understanding of the row anomaly (Schenkeveld et al., 2017), and following the flagging in the DOMINO v2 data product. In addition, the data of coarse spatial resolution from rows 1-5 and rows 56-60 are also excluded, as suggested by Lamsal et al. (2015). Furthermore, we exclude OMI data with cloud fraction > 0.3 to minimize retrieval uncertainties due to clouds and aerosols (Boersma et al., 2011; Lin et al., 2014).

Fig. 2a shows that there is an apparent increasing trend of the averaged tropospheric SCDs in the remote ocean region (Fig. 2b) with minimal marine traffic. This trend reflects the increase in the magnitude of the stripes (step-wise SCD variability from one row to another) in time, which originates from the use of a constant (2005-averaged) solar irradiance reference spectrum in the DOAS spectral fits throughout the mission and the weak increase of noise in the OMI radiance measurements (Boersma, personal communication, 2017; Zara et al., 2018). Fig. 2a shows that there is a positive annual trend of $1.75\pm0.45\times10^{13}$ molecules cm$^{-2}$ yr$^{-1}$. The ocean trend is insensitive to the region selection in the remote North Pacific (varies within 10%). We only analyze OMI tropospheric column trends over the CONUS for grid cells with 2005-
2014 averaged VCDs > $1 \times 10^{15}$ molecules cm$^{-2}$, which tends to minimize the effect of the background noise. However, removing this background ocean (absolute) trend has a non-negligible effect in reducing the OMI relative trend (Fig. 1). We refer to such derived (relative) trend data as “Ocean”. An alternative method is to subtract monthly SCDs of the remote ocean region from the OMI tropospheric SCD data. Although the end results are essentially the same as the trend removal method, noises are added to the SCD data (Fig. 2a), making it more difficult to understand the effects of the MODIS albedo update and the lightning filter (next sections). We therefore choose to use the (absolute) trend removal method here.

2.3.2 MODIS albedo update

The albedo data used to calculate the $AMF_T$ in “Standard” and “Ocean” versions of trend analysis are from the DOMINO v2 products, which are the climatology of averaged OMI measurements during 2005-2009 with a spatial resolution of 0.5°×0.5° (Kleipool et al., 2008) and is valid for 440 nm. We recalculate the $AMF_T$ using the MODIS 16-day MCD43B3 albedo product with 1km spatial resolution, which combines data from both MODIS onboard Aqua and Terra satellites (Schaaf et al., 2002; Tang and Zhang, 2007). Aqua and Terra have an equatorial overpassing time of 13:30 LT and 10:30 LT, respectively. The band 3 (459nm-479nm) is used to match the NO$_2$ fitting window (405nm-465nm). The albedo is spatially integrated to the geometry of OMI pixels and is temporally interpolated to match OMI overpassing dates. In order to maintain the consistency of the DOMINO retrieval algorithm (Boersma et al., 2011), we only use the MODIS data to improve the temporal variations of albedo data used in the retrieval. We scale the MODIS albedo data such that the mean albedo during 2005-2009 is the same as the OMI climatology at 0.5°×0.5°. We recalculate OMI tropospheric VCDs using the MODIS albedo data as described. We recalculate the relative OMI trend and remove the ocean (absolute) trend (Section 2.3.1). We refer to this version of OMI relative trend data as “MODIS”.

2.3.3 Lightning event filter

Over North America, lightning is a major source of NOx in the free troposphere and its simulations in CTMs are uncertain (e.g., Zhao et al., 2009a; Luo et al., 2017). The large temporospatial variations of lightning NOx make it difficult to compute satellite based NO$_2$ trends by changing the vertical distributions of NO$_2$ affecting the AMF calculation (e.g., Choi et al., 2008b; Lamsal et al., 2010) and the SCD values. Given the difficulty to simulate lightning NOx accurately across different years, we use a lightning filter to remove potential effects of lightning NOx on the basis of the flash rate observations of cloud-to-ground (CG) lightning flash data detected by the National Lightning Detection Network™ (NLDN) (Cummins and Murphy, 2009; Rudlosky and Fuelberg, 2010). NLDN only reports the ground point of a CG lightning flash, while the CG lightning flash can extend horizontally to tens of kilometers. A CG lightning flash can affect the NO$_2$ retrievals not only in the model grid cell where the CG lightning is located but also the nearby model grid cells. The atmospheric lifetime of NOx in the free troposphere can be up to 1 week. Therefore, we exclude the OMI NO$_2$ data within a radius of 90 km of the NLDN-reported CG lightning location (about two
model grid cells around the grid cell where the CG lightning is located) for a period of 72 hours after the lightning occurrence. Since lightning usually occur along the track of a thunderstorm, the 90 km radius is more a constraint on lightning NOx effects across the track. The extended period of 72 hours is to ensure that we exclude data affected by lightning NOx. Figure 4 shows the distribution of the number of days of 2005-2014 with lightning detection. The Southwest monsoon and the South regions have more lightning days than the other areas. While there are fewer lightning flashes in the Northeast than the South (Fig. 3), large amounts of lightning NOx can be produced by high flash ratios of severe thunderstorms and they can be transported northward from the South to the Northeast (Choi et al., 2005). We therefore further filter OMI NO\textsubscript{2} data in the Northeast on the basis of CG lightning flash rates in the South. If the average CG flash rate in the South exceeds the 95th percentile value of the NLDN observations, which is 0.035 flash km\textsuperscript{-2} day\textsuperscript{-1} (Fig. S2 in the Supplement), we exclude in the analysis the Northeast OMI data in the following 72 hours. Excluding the OMI data based on CG lightning data implicitly removes the data affected by cloud-to-cloud lightning collocated with CG lightning. The lightning filter removes about 2%, 27%, 20%, and 19% of OMI data, which are coincident with AQS data, for the West, the Midwest, the Northeast and the South, respectively. We refer to this version of OMI relative trend data as “Lightning filter”.

3 Results and discussion

We group the analysis results into different regions: (a) West, (b) Midwest, (c) Northeast, and (d) South (Fig. 1), following the regional divisions by the United States Census Bureau. To make a fair comparison between the in situ and OMI-based trends, we only use spatially and temporally coincident in situ and OMI NO\textsubscript{2} observations in Section 3.1. We apply the Mann-Kendall method with the Sen’s slope estimator to calculate the relative trend of NO\textsubscript{2} for each season, i.e. DJF, MAM, JJA, and SON, during 2005-2014. We compute the uncertainties of the trends with the 95th percentile confidence level of 95% using the Mann-Kendall method. Note that when we compare in situ and OMI-based trends, the lightning filter also removes in situ NO\textsubscript{2} data, which are coincident with the OMI NO\textsubscript{2} data affected by lightning. This leads to slightly different in situ NO\textsubscript{2} trends between Fig. 4 and Fig. 6 (Section 3.2.3). We first compute the trends using the “Standard” OMI VCD data. The ocean trend removal, MODIS albedo update, and lightning filter are then added in sequence to compute three different OMI-based NO\textsubscript{2} trends (in addition to “Standard”) to compare to the AQS in situ results. A subtlety in the comparison is that the coincident data change when the lightning filter is applied. As a result, the AQS in situ results in this set of comparison differ from those in the other three sets.

3.1 In situ and “Standard” OMI-based trends

Fig. 4 shows that both AQS in situ and “Standard” OMI-based seasonal relative trends are negative for all seasons across the regions. OMI-based trends generally underestimate the decreasing trends by up to 3.7% yr\textsuperscript{-1} (the absolute difference between relative trends) except for the large overestimation in the Midwest and the Northeast regions during DJF. The overestimates in these two regions are 3.0% yr\textsuperscript{-1} and 1.1% yr\textsuperscript{-1},
respectively. On average, the differences between OMI-based and in situ seasonal relative trends are 1.6% yr\(^{-1}\), -0.3% yr\(^{-1}\), 1.0% yr\(^{-1}\), and 1.4% yr\(^{-1}\) for the West, the Midwest, the Northeast, and the South regions, respectively. Note that the relative trends are calculated using coincident measurements for the comparisons. The NO\(_2\) relative trends from both datasets are expected to be close on a regional basis where surface emissions of NOx dominate the observed surface concentrations and tropospheric VCDs of NO\(_2\). The focus of this work is to reconcile the difference between AQS in situ and OMI-based trends, which will be discussed in the following sections.

### 3.1.1 Improvement due to ocean trend correction

After removing the ocean trend as discussed in Section 2.3.1, the OMI-based NO\(_2\) decreasing trends are more pronounced as shown in Fig. 4 (“Ocean”, blue line) by 0.1-0.9% yr\(^{-1}\). The regional relative trends have different sensitivities to the ocean trend removal due to different tropospheric VCDs levels. In general, the discrepancies between OMI-based and in situ trends are reduced except for the Midwest and the Northeast regions during DJF, which are already biased low. The averaged differences between OMI-based and in situ seasonal relative trends for the West, the Midwest, the Northeast, and the South regions are 1.2% yr\(^{-1}\), -1.1% yr\(^{-1}\), 0.4% yr\(^{-1}\), and 1.0% yr\(^{-1}\). Only in the Midwest region, removing the ocean trend enlarges the difference due to the large winter bias.

### 3.1.2 Improvement due to MODIS albedo update

The adoption of the up-to-date MODIS albedo (Section 2.3.2) greatly reduces the difference of relative trends in the Midwest during DJF from -3.6% yr\(^{-1}\) (“Ocean”) to 1.3% yr\(^{-1}\) (“MODIS”), the improvement of DJF trend difference is more moderate from -1.7% to 0.5% (Fig. 4). There are no significant changes of the comparisons in other regions or other seasons. Fig. 5 shows the albedo seasonal relative trends for the 4 regions coincident with AQS in situ NO\(_2\) data. The OMI DOMINO v2 incorporates a climatology albedo dataset (Kleipool et al., 2008) with snow/ice albedo adjustment using the NASA Near-real-time Ice and Snow Extent (NISE) dataset (Boersma et al., 2011). The climatology albedo data exhibits no trends. Thus, the trends of albedo mainly originate from the yearly variation of NISE detected snow/ice, followed by OMI sampling variation. The noticeable seasonal trend of the OMI DOMINO v2 albedo dataset is the 3.9% yr\(^{-1}\) increase in DJF of the Midwest and a smaller DJF increase (1.0%) of the Northeast. In contrast, the MODIS albedo dataset exhibits a smaller positive DJF trend (0.8% yr\(^{-1}\)), 3.1% yr\(^{-1}\) less than the trend from DOMINO v2, in the Midwest, and a small negative DJF trend (-0.8%) in the Northeast. The comparison to the AQS data shows that the MODIS albedo update leads to better agreement between satellite and in situ trends in winter in these regions (Fig. 4).

### 3.1.3 Improvement due to lightning filter

As discussed in Section 2.3.3, lightning NOx affects the retrievals of satellite tropospheric NO\(_2\) VCDs. Fig. 6 shows that the lightning filter significantly reduces the difference between the OMI-based relative trend
and that of the AQS data by 0.5-1.4% yr\(^{-1}\) in the Northeast and 0.9-1.3% yr\(^{-1}\) in the South. As a result, the seasonal trend differences are within 0.9% yr\(^{-1}\) in these two regions except during SON. The lightning filter has little effect on the West and the Midwest. While lightning NO\(_x\) can be significant during the monsoon season in some regions of the West (Fig. 3), the average tropospheric NO\(_2\) VCDs are usually < 1\times 10^{15}\) molecules cm\(^{-2}\) and lightning affected regions are therefore excluded in trend analysis.

The effect of lightning filter (Fig. 6) cannot be shown in Fig. 4 because the coincident OMI and AQS data points are fewer after applying the lightning filter. We examine the improvements of ocean trend removal, MODIS albedo update, and lightning filter by comparing the differences of different OMI-based seasonal relative trends from the AQS in situ trends in Fig. 7. The previously discussed improvements such as OMI albedo update for the Midwest and the Northeast during DJF are shown. By subtracting the AQS trends, we can now find clear improvements of the lightning filter for the South and the Northeast. There remains seasonal variation of OMI-based trend biases relative to in situ data but the discrepancies of the annual trends after the three discussed procedures are relatively small at 0.3% yr\(^{-1}\), -0.3% yr\(^{-1}\), -0.1% yr\(^{-1}\), and 0.0% yr\(^{-1}\), in the West, the Midwest, the Northeast, and the South regions (Fig. 1), respectively. The remaining seasonal difference of the trends reflects in part the nonlinear photochemistry (Gu et al., 2013) and the effects of NO\(_x\) emission changes on NO\(_2\) retrievals (Lamsal et al., 2015).

### 3.2 OMI-based NO\(_2\) trends

Table 1 summarizes the regional annual trends of coincident AQS in situ and OMI data. The “Standard” OMI data (following the DOMINO v2 algorithm) tend to show less NO\(_2\) reduction than AQS data. After applying the three corrections discussed in the previous section to the OMI data, the agreement with the AQS trends is within the uncertainties of the trends. While lightning NO\(_x\) is part of OMI NO\(_2\) observations, we treat the influence of lightning on the OMI tropospheric VCD trend as a bias for comparison purposes in this study since AQS data are not as strongly affected by lightning.

Without the lightning filter, AQS decreasing trends are stronger while the decreasing trends of OMI data are less (Fig. 7). The lightning trend in the NLDN data is unclear due in part to the changing instrument sensitivity (Koshak et al., 2015). If lightning NO\(_x\) is not accounted for in OMI retrieval, tropospheric NO\(_2\) VCDs are overestimated. On the other hand, lightning accompanies low pressure systems which mix the atmosphere vertically and tend to reduce surface NO\(_2\) concentrations when anthropogenic emissions are high such as urban and suburban regions. Therefore, lightning has opposite effects on surface and satellite trends. The low-pressure dilution effect on surface NO\(_2\) concentrations depends on anthropogenic emissions (since the end point of dilution is the background NO\(_2\) value). Therefore, the reduction of weaker decreasing surface trends likely reflects a reduction of low-pressure dilution effect. Similarly, as anthropogenic emissions decrease, the positive bias of tropospheric VCDs due to lightning NO\(_x\) becomes larger, likely resulting in a reduction of weaker decreasing trends. We consider the lightning effects on surface NO\(_2\) trends to be mostly meteorological driven not by lightning NO\(_x\) directly (e.g., Ott et al., 2010; Lu et al., 2017) and hence the corrected filtered OMI NO\(_2\) data are likely closer to emission related concentration changes.
The AQS in situ NO\textsubscript{2} annual relative trends (coincident with OMI data with lightning filter) are most significant in the Northeast (-5.2±0.6% yr\textsuperscript{-1}) and the West (-4.2±0.5% yr\textsuperscript{-1}), followed by the South (-3.0±0.5% yr\textsuperscript{-1}) and the Midwest (-2.8±0.6% yr\textsuperscript{-1}) regions. The nationwide annual trend is -4.1±0.4% yr\textsuperscript{-1}, which is consistent with the previous studies (Lamsal et al., 2015; Lu et al., 2015; Tong et al., 2015; de Foy et al., 2016b; Duncan et al., 2016; Krotkov et al., 2016). The significant NO\textsubscript{2} reductions result from updated technologies and strict regulations (Krotkov, et al., 2016). The corrected OMI-based NO\textsubscript{2} trends (coincident with AQS data) show similar reduction rates in the West (-3.8±0.4% yr\textsuperscript{-1}), the Midwest (-3.1±0.5% yr\textsuperscript{-1}), the Northeast (-5.3±0.7% yr\textsuperscript{-1}) and the South (-3.0±0.5% yr\textsuperscript{-1}) regions. The nationwide annual trend is -3.9±0.3% yr\textsuperscript{-1}.

One advantage of satellite observations over a surface monitoring network is spatial coverage. The OMI data (“Lightning filter”) coincident with the AQS data show a national annual trend of -3.9±0.3% yr\textsuperscript{-1} similar to the AQS in situ trend of -4.1±0.4% yr\textsuperscript{-1}. Using all data available (Fig. 8, Table 1), the OMI data (“Lightning filter”) show a much lower trend of -1.5±0.2%yr\textsuperscript{-1}, about half of the AQS trend (-3.9±0.4% yr\textsuperscript{-1}). Fig. 9 shows that the AQS sites, which are mostly urban and suburban sites, tend to be located in regions with high tropospheric NO\textsubscript{2} VCDs. The OMI decreasing trend with corrected data is a function of tropospheric NO\textsubscript{2} VCDs, increasing from 0% yr\textsuperscript{-1} to -6% yr\textsuperscript{-1} (Fig. 9). The national annual trend is close to the value of clean regions which contribute much more than polluted regions. The larger decrease near the anthropogenic source regions reflect in part the nonlinear photochemistry (Gu et al., 2013) and in part to a stronger influence of NO\textsubscript{x} sources such as soils in rural regions.

4. Conclusions

Using data from the DOMINO v2 algorithm, we find that the computed OMI-based seasonal NO\textsubscript{2} (relative) trends underestimate the decreasing trends of the EPA AQS data by up to 3.7% yr\textsuperscript{-1}. We attribute most of the discrepancies to OMI retrievals since the standard retrieval algorithm was not specifically designed for trend analysis. While lightning NO\textsubscript{x} is part of OMI NO\textsubscript{2} observations, we treat the influence of lightning on the OMI tropospheric VCD trend as a bias for comparison purposes in this study since AQS data are not as strongly affected by lightning. Furthermore, lightning NO\textsubscript{x} effects need to be removed when using satellite observations to understand the effects of changing anthropogenic emissions.

In this study, we show that removing the background ocean trend (likely a result of the increasing stripes), adopting MODIS albedo data (with better temporospatial resolutions), and excluding lightning influences can bring OMI tropospheric NO\textsubscript{2} VCD trends in close agreement (within 0.3% yr\textsuperscript{-1}) with those of the AQS data. The largest effects of MODIS albedo update are in winter in Midwest and Northeast and those of lightning filter are in the South and the Northeast. After applying these corrections, the derived OMI-based annual regional NO\textsubscript{2} trends change by a factor of > 2 for the South, the Midwest, and the West and seasonal changes can be even larger. We derive optimized OMI-based NO\textsubscript{2} regional annual relative trends using all available data for the West (-2.0%±0.3 yr\textsuperscript{-1}), the Midwest (-1.8%±0.4 yr\textsuperscript{-1}), the Northeast (-3.1%±0.5 yr\textsuperscript{-1}), and the South (-0.9%±0.3 yr\textsuperscript{-1}).
The national annual trend of the corrected OMI data is \(-1.5\pm 0.2\% \text{yr}^{-1}\), about half of the AQS trend (-3.9\pm 0.4\% \text{yr}^{-1}). It reflects that the AQS sites are mostly located in the urban and suburban regions, where OMI data show much larger decreasing trends (up to \(-6\% \text{yr}^{-1}\)) than rural regions (down to 0\% \text{yr}^{-1}). The reasons for the dependence of OMI derived trends on tropospheric \(\text{NO}_2\) VCDs and the seasonal/regional trend differences are still not completely understood. Further studies are necessary to improve our understanding of these trends. The observation-based lightning filter implemented in this study is preliminary. Incorporating chemical transport modeling may improve this filter. Moreover, the results presented here represent an alternative and indirect way to assess the importance of lightning NOx for National Climate Assessment (NCA) analyses described in Koshak et al. (2015), and Koshak (2017). Inversion studies (e.g., Zhao and Wang, 2009; Gu et al., 2013, 2014, 2016) will be needed to understand quantify the emission and AMF changes corresponding to the OMI tropospheric \(\text{NO}_2\) VCD trends.

Figure 1. The solid black borders in the center map define the four regions used in this study. The colored background shows the OMI-based NO2 annual relative trends of the “lightning filter” data. Grid cells with 2005-2014 mean NO2 VCD values < $1 \times 10^{15}$ molecules cm$^{-2}$ are excluded in this study and are shown in white. The black bordered circles represent the locations of AQS sites. Panel (a) through (d) show the regional difference (OMI-based relative trends minus AQS relative trends) of annual relative trends between coincident OMI-based and AQS in situ data. The colored diamonds are for “Standard” (orange), “Ocean” (blue), “MODIS” (green), and “Lightning filter” (red) OMI data, respectively. The different OMI VCD data are described in Section 2.4.
Figure 2. The black line in panel (a) shows the monthly averaged OMI tropospheric NO$_2$ VCD values in the North Pacific region (red box in panel (b)) from 2005 to 2014. The red line in panel (a) represents the ocean trend used in this research, with the 95$\%$ confidence intervals shaded in red.
Figure 3. Number of days with NLDN detected cloud-to-ground (CG) lightning per model grid cell per year during 2005-2014. The lightning occurrences are calculated using the REAM grid resolution.
Figure 4. Seasonal relative trends of NO₂ calculated from the AQS in situ measurements ("AQS", black line) and those derived from different OMI VCD data ("Standard", orange line; "Ocean", blue line; "MODIS", green line). The error bars represent 95% percentile confidence intervals.
Figure 5. Seasonal relative albedo trends of OMI (black line) and MODIS (red line) surface reflectance products, coincident with AQS in situ data used in Figure 5. The error bars represent 95th percentile confidence intervals.
Figure 6. Same as Figure 5 but for coincident seasonal relative trends of NO\textsubscript{2} calculated from the AQS (in situ measurements ("AQS", black line) and those derived from OMI data (red line) after applying the lightning filter ("OMI (lightning filter)", red line). The error bars represent 95\textsuperscript{th} percentile confidence intervals. The coincident data points are less than those used in Figure 5 and therefore the AQS trends are not the same.
Figure 7. Seasonal differences of OMI-based relative trends from those computed from AQS in situ data. The error bars represent 95th percentile confidence intervals. The relative trends are shown in Figs. 6 and 8. The figure legends are the same as in Figs. 6 and 8 but with the AQS trends subtracted from the OMI-based trends.
Figure 8: Annual relative trends of OMI-based NO\textsubscript{2} for “Standard” (a) and for “Lightning filter” (b) as the colored background. Black bordered circles indicate corresponding AQS NO\textsubscript{2} trends. Grid cells with 2005-2014 mean NO\textsubscript{2} VCDs < 1x10\textsuperscript{15} molecules cm\textsuperscript{-2} are excluded in the analysis and are shown in white.
Figure 9. (a) The “Lightning filter” OMI-based NO$_2$ relative trend as a function 2005-2014 averaged OMI tropospheric NO$_2$ VCD binned every $1 \times 10^{15}$ molec/cm$^2$. The error bars represent 95th percentile confidence intervals. The red line shows a least-squares regression. (b) The distribution of 2005-2014 averaged OMI tropospheric NO$_2$ VCD. Black bordered circles represent AQS sites. The corrected OMI tropospheric NO$_2$ data (“Lightning filter”) are used.
