11 **Abstract**

12 Reactive mercury (RM) is an important component of the global atmospheric mercury cycle, but
13 measurement currently depends on un-calibrated, operationally defined methods with large
14 uncertainty and demonstrated interferences and artifacts. Cation exchange membranes (CEM)
15 provide a promising alternative methodology for quantification of RM, but method validation
16 and improvement are ongoing. For the CEM material to be reliable, uptake of gaseous elemental
17 mercury (GEM) must be negligible for all conditions, and RM compounds must be captured and
18 retained with high efficiency. In this study the performance of CEM material under exposure to
19 high concentrations of GEM ($1.43 \times 10^6 - 1.85 \times 10^6 \text{ pg m}^{-3}$) and reactive gaseous mercury
20 bromide ($\text{HgBr}_2 \sim 5000 \text{ pg m}^{-3}$) was explored, using a custom-built mercury vapor permeation
21 system, with quantification of total permeated Hg accomplished via pyrolysis at 600 °C and
22 detection using a Tekran[®] 2537A. Permeation tests were conducted for 24 to 72 hours in clean
23 laboratory air, with absolute humidity levels ranging from 0.1 – 10 g m⁻³ water vapor. Gaseous
24 elemental mercury uptake by the CEM material averaged no more than 0.004% of total exposure
25 for all test conditions, which equates to a non-detectable GEM artifact for typical ambient air
26 sample concentrations. Recovery of HgBr₂ on CEM filters was >100 % compared to calculated
27 total permeated HgBr₂, suggesting incomplete thermal decomposition at the pyrolyzer, as the

28 CEM material collected HgBr₂ with less than 1% downstream breakthrough on average,
29 implying a high collection efficiency.

30

31 **1 Introduction**

32 Mercury (Hg) is a persistent environmental contaminant with a significant atmospheric life time,
33 and the form and chemistry of Hg is an important determinant of its biogeochemical cycling.

34 Mercury in the atmosphere is found in three forms: gaseous elemental mercury (GEM), gaseous
35 oxidized mercury (GOM), and particulate bound mercury (PBM). PBM and GOM are often
36 quantified together as reactive mercury (RM = GOM + PBM). Atmospheric GEM, at an average
37 global background concentration of 1 – 2 ng m⁻³, can be reliably measured with calibrated
38 analytical instruments (Gustin et al., 2015; Slemr et al., 2015). The measurement of GOM and
39 PBM requires detection at the part per trillion (pg m⁻³) level and depends on un-calibrated
40 operationally defined methods with demonstrated interferences and artifacts, and concomitant
41 large uncertainty. Recent reviews (Gustin et al., 2015; Zhang et al., 2017) detail the
42 shortcomings, difficulties, and needed developments for atmospheric RM measurements.

43 As an alternative methodology, cation exchange membranes (CEM) have been used to
44 selectively measure GOM concentrations in ambient air (Huang et al., 2013; Huang and Gustin,
45 2015b; Huang et al., 2017; Sheu and Mason, 2001; Pierce and Gustin, 2017; Maruszczak et al.,
46 2017; Ebinghaus et al., 1999; Mason et al., 1997; Bloom et al., 1996). The use of CEM type filters
47 for this purpose was first documented in the literature in a conference presentation (Bloom et al.,
48 1996), although such membranes (then referred to as ‘ion exchange membranes’) were deployed
49 earlier in a field-based international comparative study of RM measurement techniques in
50 September, 1995 (Ebinghaus et al., 1999). In the comparative study, one participating lab

51 deployed a series of ion exchange membranes (for GOM) behind a quartz fiber filter (for PBM)
52 at a sample flow rate of 9-10 Lpm, for 24 h measurements (filter pore sizes were not reported).
53 Results for PBM and GOM were in similar ranges of 4.5 – 26 pg m^{-3} and 13-23 pg m^{-3} ,
54 respectively (Ebinghaus et al., 1999).

55 The ion exchange membrane method was also applied in a 1995-96 field campaign for
56 determining the speciation of atmospheric Hg in the Chesapeake Bay area (Mason et al., 1997).
57 This study used a 5-stage Teflon filter pack system that included one up front quartz fiber filter
58 (0.8 μm pore size) to remove particulate, and four downstream Gelman ion exchange membranes
59 (pore size not reported) to 1) capture GOM, 2) capture GOM breakthrough, 3) serve as
60 deployment blanks, and 4) isolate the filter train on the downstream side (Mason et al., 1997).
61 Concentrations of GOM were reported to be 5 – 10 pg m^{-3} , essentially at or below the method
62 detection limit and it was speculated that even this small amount may have been an artifact from
63 fine particulate Hg passing through the 0.8 μm quartz fiber filter (Mason et al., 1997). The 3rd-in-
64 series ion exchange membrane blanks were reported to be not significantly different in Hg
65 concentration from unused membrane material, indicating that breakthrough was not a
66 phenomenon that extended past the second ion exchange filter position.

67 The particulate Hg artifact problem was subsequently elaborated on in a further comparative
68 study focusing exclusively on RM measurement techniques. Specific concerns included physical
69 particle breakthrough, re-evolution of gas-phase Hg^{2+} from PBM captured on the upstream
70 particulate filters passing downstream to the ion exchange membranes, possible adsorption of
71 GOM compounds to the particulate filters, or a GEM collection artifact on the ion exchange
72 membranes (Sheu and Mason, 2001). None of these concerns were proven or disproven
73 conclusively.

74 Recent CEM based sampling systems typically deploy a pair of CEM disc filters without a pre-
75 particulate filter, in replicates of 2 to 3 at a flow rate of 1.0 Lpm (Gustin et al., 2016). Each pair
76 of filters constitutes one sample, the first filter serving as the primary RM collection surface, and
77 the second filter capturing breakthrough. Filters are deployed for 1-to-2 weeks and then collected
78 for analysis (CVAFS, EPA Method 1631, modified) (Huang et al., 2017). The CEM material
79 consists of a positively charged polyethersulfone coated matrix (Pall Corporation), and at least
80 one manufacturing evolution has occurred (Huang and Gustin, 2015a). Prior CEM material
81 versions (I.C.E. 450) had a pore size of 0.45 μm , while the current CEM material (Mustang[®] S)
82 has a manufacturer reported pore size of 0.8 μm .

83 Previous work with the I.C.E 450 material indicated it does not adsorb significant quantities of
84 GEM in passive exposures, but can selectively uptake gas-phase Hg^{2+} species (Lyman et al.,
85 2007). The CEM material was subsequently adapted for use in active sample flow systems, with
86 the presumption of continued inertness to GEM and selectivity for GOM (Huang et al.,
87 2013;Huang and Gustin, 2015b). These studies and others (Lyman et al., 2016) have shown
88 better GOM recovery on CEM material compared to potassium chloride (KCl) coated denuder
89 methods.

90 Despite these tests, the transparency of the CEM material to GEM uptake has not been
91 conclusively demonstrated for active sampling flow rates, nor for high GEM concentrations,
92 though limited data using low concentration manual Hg^0 injections through CEM filters suggests
93 little or no GEM uptake (Lyman et al., 2016). However, even small rates of GEM uptake by the
94 CEM material could result in a significant measurement artifact (e.g. a modest 1 – 2% GEM
95 uptake could easily overwhelm detection of typical ambient GOM concentrations). It is therefore
96 of critical importance that such a GEM artifact be ruled out if the CEM material is to be

97 successfully deployed for ambient RM measurements, first and foremost under controlled
98 laboratory conditions in the absence of confounding variables.

99 Additionally, previous studies have observed significant amounts of “breakthrough” GOM on the
100 secondary filter. The amount of breakthrough is not consistent, neither as a constant mass, with
101 total Hg ranging from zero to as high as 400 pg (Huang et al., 2017), nor as a percentage of Hg
102 collected on the primary filter, ranging from 0 – 40% (Pierce and Gustin, 2017). Similar variable
103 breakthrough issues were observed in the earliest field-based CEM measurements as well
104 (Mason et al., 1997). In contrast to ambient measurements, previous laboratory experiments have
105 reported only minor (0 – 16%) or no breakthrough (Huang et al., 2013; Huang and Gustin,
106 2015b). Limited experimental work with flow rates of 1.0 and 16.7 Lpm in ambient air could not
107 provide an explanation for differing breakthrough rates (Pierce and Gustin, 2017).

108 In this paper we investigate the potential for GEM uptake on CEM material using a custom-built
109 permeation system. In addition, the ability of the CEM material to capture and retain a
110 representative GOM compound (mercury bromide, HgBr_2) is discussed with a view to estimate
111 collection efficiency and explain or rule out possible mechanisms of breakthrough for both dry
112 and humid conditions.

113 **2 Methods**

114 A Tekran[®] 2537A ambient mercury analyzer was integrated with a custom-built permeation
115 system designed to enable controlled exposures of GEM and GOM to CEM filters (Fig. 1). The
116 2537A analyzer was calibrated at the beginning and periodically throughout the study and
117 checked for accuracy by manual Hg^0 injections (mean recovery $101.1\% \pm 4.3$, $n = 10$, SI Fig. 1).
118 The entire system was checked for Hg contamination in clean air prior to permeation tests, and

119 periodically during sampling (SI Fig. 2). All tubing and connections used in the permeation
120 system were polytetrafluoroethylene (PTFE), except for the quartz glass pyrolyzer tube and
121 perfluoroalkoxy (PFA) filter holders. Each of these materials is known to be chemically inert,
122 virtually nonporous, and to have a low coefficient of friction. For these reasons, PTFE/PFA
123 plastic and quartz glass are the standard materials employed in almost all Hg sampling systems,
124 as GEM passes over or through these surfaces without loss (Gustin et al., 2015). Given its
125 reactive nature, some GOM inevitably adsorbs to internal line surfaces, but the capacity of these
126 materials to sorb and retain GOM is not infinite and a steady state of adsorption/desorption is
127 expected after 5-6 hours of exposure to a stable concentration (Xiao et al., 1997;Gustin et al.,
128 2013).

129 Sample flow through the system was alternated between two PTFE sample lines (designated
130 Line 0 and Line 1) using a Tekran[®] Automated Dual Switching (TADS) unit. Sample air was
131 constantly pulled through each line at 1.0 Lpm by the internal pump and mass flow controller in
132 the 2537A, or by an external flush pump (KNF Laboport[®] N86 KNP) and mass flow controller
133 (Sierra Smart-Trak[®] 2). Laboratory air was pulled through a single inlet at the combined rate of
134 2.0 Lpm, passing through a 0.2 μm PTFE particulate filter and an activated charcoal scrubber to
135 produce clean sample air. Additionally, for dry air permeations sample air was pulled through a
136 Tekran[®] 1102 Air Dryer installed upstream of the particulate filter, and for elevated humidity
137 permeations sample air was pulled through the headspace of a distilled water bath (DIW, < 0.2
138 ng L⁻¹ total Hg) that was located upstream from the charcoal scrubber to eliminate the DIW being
139 a potential Hg source to the system. Temperature and relative humidity (RH) were measured in-
140 line (Campbell Scientific CS215) and used for calculation of absolute humidity.

141 Pure liquid Hg⁰ and crystalline HgBr₂ (purity > 99.998% Sigma-Aldrich[®]) were used as Hg
142 vapor sources. The elemental Hg⁰ bead was contained in a PTFE vial. Solid HgBr₂ crystals were
143 packed in thin-walled PTFE heat-shrink tubing (O.D. 0.635 cm) with solid Teflon plugs in both
144 ends to create a perm tube with an active permeation length of 2 mm (Huang et al., 2013). The
145 HgBr₂ permeation tube was also placed in the bottom of a PTFE vial, and the permeation vials
146 were submerged in a temperature-controlled laboratory chiller (0.06 ± 0.13 °C, Cole Parmer
147 Polystat[®]). A low source temperature was favored both because higher temperatures would have
148 produced unacceptably high concentrations, and because there is evidence that at higher
149 temperatures a small amount of Hg⁰ can be evolved from Hg²⁺ compounds (Xiao et al., 1997).

150 An ultra-high purity nitrogen (N₂) carrier gas was passed through the permeation vials at 0.2
151 Lpm to carry the target Hg vapor into the main sample line through a PTFE T-junction. The main
152 sample line was split into Line 0 and Line 1 immediately downstream from the permeation flow
153 junction. Line 0 proceeded directly to the 2537A without modification during GEM permeations
154 (Fig. 1A), but housed CEM filters during the HgBr₂ permeations (Fig. 1B, 1C). Line 1 held a
155 pyrolyzer unit composed of a quartz glass tube (O.D. 0.625 cm) packed with a 3 cm section of
156 quartz wool heated to 600 °C using a nichrome wire coil (SI Fig. 3 and discussion). The goal of
157 the pyrolyzer was to convert all Hg to GEM for detection on the Tekran[®] 2537A.

158 CEM filters were deployed in 2-stage, 47 mm disc PFA filter holders (Savillelex[®]). The primary
159 “A” filter in the 2-stage holder is the first to be exposed to the permeated Hg, with the secondary
160 “B” filter mounted immediately behind the A filter (A to B distance ~ 3mm) to measure potential
161 breakthrough. For GEM permeations, three 2-stage filter holders were placed in-series on Line 1
162 behind the pyrolyzer unit (Fig. 1A), while total Hg coming through the system was measured on
163 Line 0 with no filters in place. This allowed simultaneous exposure of 6 CEM filters in one GEM

164 sample exposure. The first CEM filter in-line served to scrub any small residual RM passing
165 through the system and pyrolyzer, and these first in-line filters were removed for the calculations
166 of GEM uptake (SI Fig. 4 and discussion).

167 For determining the potential for GOM breakthrough, two system configurations were used. In
168 the first configuration (Fig. 1B), the total Hg concentration of air that passed through the
169 pyrolyzer on Line 1 was measured without any filters, while Line 0 held one 2-stage CEM filter
170 pair for HgBr₂ loading. This configuration allowed for real time (10 min interval) quantification
171 of the HgBr₂ permeation concentration through Line 1 using the 2537A, and comparison with
172 total Hg loading on the CEM filters on Line 0. In the second configuration, replicate filters were
173 concurrently loaded with HgBr₂ by placing 2-stage CEM filter holders on both Line 0 and Line 1
174 (upstream of the pyrolyzer, Fig. 1C). In all HgBr₂ exposures, the filter holders were placed as
175 close to the permeation vial as possible, with a total distance from vial to filter surface of
176 approximately 20 cm. Mercury bromide permeation was conducted in dry air and elevated
177 humidity air. The difference between one line being fully open to the HgBr₂ permeation flow
178 (configuration Fig. 1B) and then closed by deployment of the CEM filters (configuration Fig.
179 1C) enabled a rough determination of the amount of HgBr₂ line-loss within the system.

180 After permeation, CEM filters were collected into clean, sterile polypropylene vials and analyzed
181 for total Hg by digestion in an oxidizing acid solution, reduction to Hg⁰, gold amalgamation, and
182 final quantification by cold vapor atomic fluorescence spectrometry (CVAFS, EPA Method
183 1631, Rev. E) using a Tekran[®] 2600 system. This analysis provided for comparison of total Hg
184 filter loading, and verification of in-line results. A to B filter breakthrough was calculated by
185 comparison of total Hg recoveries on the primary and secondary CEM filters, using Eq. (1):

186
$$\% \text{ Breakthrough} = 100 * CEM_{2nd} / (CEM_{1st} + CEM_{2nd}) \quad (1)$$

187 Blank CEM filters were collected and analyzed in the same manner with every set of sample
188 filters deployed on the permeation system, and the mean filter blank value was subtracted from
189 all total Hg values to calculate the final blank-corrected Hg values used for data analysis. All
190 data were analyzed in Microsoft® Excel (version 16.12) and RStudio® (version 3.2.2).

191 **3 Results**

192 **3.1 Elemental Mercury Uptake on CEM Filters**

193 Elemental Hg uptake on CEM material was negligible for permeated Hg⁰ vapor concentrations
194 ranging from $1.43 \times 10^6 - 1.85 \times 10^6$ pg m⁻³ (Fig. 2). High GEM concentrations were employed in
195 this study under the logic that if no GEM uptake was observed at high concentrations, a similar
196 lack of GEM uptake can be expected for all lower concentrations.

197 The mean Hg mass on blank CEM filters was 50 ± 20 pg ($n = 28$). For permeations into dry
198 sample air of 0.5 ± 0.1 g m⁻³ water vapor (WV), total mean Hg⁰ permeation exposures of 2.7×10^6
199 pg (24 h) and 7.3×10^6 pg (72 h) resulted in total (blank-corrected) Hg recoveries on the CEM
200 filters of 100 ± 40 pg ($n = 10$) and 280 ± 110 pg ($n = 5$), respectively. These quantities of total
201 recovered Hg equate to a mean GEM uptake rate on the CEM filters of $0.004 \pm 0.002\%$. For
202 GEM permeations into ambient humidity sample air ($2 - 4$ g m⁻³ WV), at a slightly lower total
203 mean permeated Hg⁰ 24 h exposure of 2.1×10^6 pg, total (blank-corrected) Hg recoveries on the
204 CEM filters were 55 ± 30 pg ($n = 10$), equating to a GEM uptake rate of $0.003 \pm 0.001\%$. The
205 overall GEM uptake rate was linear ($r^2 = 0.97$) for the range of concentrations used in this study,
206 indicating a similar low uptake rate can be expected down to lower GEM concentrations.

207 **3.2 Mercury Bromide Uptake on CEM Filters**

208 Breakthrough of HgBr₂ vapor from the primary (A) to secondary (B) CEM filters was low for all
209 conditions tested in this study (Table 1). These conditions included HgBr₂ permeated into clean
210 dry laboratory air with < 0.5 g m⁻³ WV, clean air at ambient room humidity (4 – 5 g m⁻³ WV),
211 and clean air at elevated humidity (10 – 11 g m⁻³ WV), at line temperatures between 17 to 19 °C.
212 Overall, the mean A to B filter breakthrough ranged from 0 to 0.5% and averaged 0.2 ± 0.2 % (n
213 = 17), with no statistical difference observed in mean breakthrough rates for the three levels of
214 humidity (ANOVA, p = 0.124).

215 The first HgBr₂ permeation in clean dry (< 0.5 g m⁻³ WV) laboratory air was over a 96 h period,
216 using the system configuration in Figure 1B to establish an approximately permeation rate (Fig.
217 3). Total Hg reaching the 2537A through the pyrolyzer on Line 1 (red line, Fig. 3) indicates an
218 average HgBr₂ exposure concentration of 4540 pg m⁻³, or about 4.5 pg min⁻¹ from the permeation
219 tube. After this permeation, total blank-corrected HgBr₂ loading on the primary CEM filter on
220 Line 0 was 49400 pg, but only 50 pg on the secondary CEM filter, indicating a breakthrough rate
221 of approximately 0.1%. Total Hg reaching the 2537A through the CEM filters on Line 0 (black
222 line, Fig. 3) over this time period was 15 pg, mostly at the beginning of the deployment when
223 some ambient Hg entered the opened system. The low concentrations of Hg measured
224 downstream in Line 0 on the 2537A corroborates that breakthrough of HgBr₂ was low. These
225 data also demonstrate that the CEM material did not saturate with a HgBr₂ loading of ~ 50000
226 pg, a loading far higher than could be expected in ambient conditions.

227 Subsequent replicate 24 h HgBr₂ permeations in clean dry air resulted in consistent total Hg
228 loading on CEM filters placed on both lines concurrently (8560 ± 320 pg, n = 6, Samples 2-7

229 Table 1), and mean total Hg on the secondary CEM filters was 20 ± 10 pg (average
230 breakthrough of 0.3%). On Line 0 (black line, Fig.3), which was never open to HgBr₂ vapor
231 downstream from the CEM filters at any point in the study, Hg measured at the 2537A was zero
232 for all three 24 h permeations, indicating no breakthrough (Samples 2, 4, & 6, Table 1).
233 However, on Line 1, which had been exposed to the full HgBr₂ vapor concentration of 4540 pg
234 m⁻³ over the duration of the 96 h perm test, 1155 pg of Hg were measured downstream in the first
235 24 h sample (Sample 3, Table 1). The amount of downstream Hg dropped to 10 pg in the second
236 24 h, and 6 pg in the third 24 h (Samples 5 & 7, Table 1). This downstream Hg in Line 1
237 (compared to the zero Hg simultaneously observed on Line 0) is attributed to re-volatilization of
238 HgBr₂ that had stuck to the line material during the open permeation flow. At the moment CEM
239 filters were deployed on Line 1 (red-to-blue transition, Fig. 3), a rapid asymptotic decline in the
240 Hg signal began. This decay curve supports drawdown and depletion of a Hg reservoir on the
241 interior line surfaces behind the CEM filters, and not a continuous source such as breakthrough
242 from the permeation tube that was still supplying HgBr₂ to both sample lines. The total mass of
243 Hg re-volatilized from the interior line surfaces (1155 pg) represents 4 – 5% of the total HgBr₂ that
244 had passed through Line 1 (~25000 pg based on 2537A measurement). Eventually, Hg reaching
245 the 2537A through Line 1 decreased to zero during the same 24 h filter deployment, indicating a
246 majority of HgBr₂ line contamination can be expected to flush out within ~12 h.

247 Additional HgBr₂ permeations were made at two levels of in-line humidity. At ambient room
248 humidity (4 – 5 g m⁻³ WV), mean total Hg measured on the CEM filters was 7910 ± 520 pg (n =
249 4; Samples H2-5, Table 1), with an average breakthrough to the secondary filters of 0.3%. When
250 normalized for sample volume, the mean HgBr₂ loading on CEM filters during ambient humidity
251 (5968 ± 125 pg) and dry air (5995 ± 188 pg) permeations was not statistically significantly

252 different (t-test $p = 0.790$). HgBr_2 breakthrough rates were also the same (0.3%) as during the
253 dry air permeations, indicating that the permeation system was operating similarly at the two
254 humidity levels, and suggesting that absolute humidity concentrations around $4 - 5 \text{ g m}^{-3} \text{ WV}$
255 have insignificant effects on collection of HgBr_2 in clean laboratory air by the CEM material.

256 We observed that an increase in humidity resulted in an initial large increase in Hg measured at
257 the 2537A downstream of the CEM filters on Line 0 (Sample H1, Table 1), concurrently with an
258 open HgBr_2 permeation flow through Line 1 while both lines were subjected to increased RH.
259 This downstream Hg on Line 0 dropped substantially to zero in ~ 10 h in the first 24 h
260 deployment (Sample H2, Table 1), and was zero for the duration of the second 24 h deployment
261 (Sample H4, Table 1). As this downstream Hg rapidly declined to zero, we believe this was also
262 an off-gassing effect, likely induced by the increased humidity, which perhaps facilitated a
263 heterogeneous surface reduction of HgBr_2 to GEM in the short section of line between the perm
264 source and CEM filters, with the GEM then passing through to the 2537A. As the breakthrough
265 rate and the mean HgBr_2 loading on the CEM filters did not change between the dry air and
266 ambient humidity permeations, the downstream Hg observed at the 2537A during the ambient
267 humidity permeations cannot be attributed to a loss of Hg from the CEM filters and is more
268 likely due to a process in the sample lines.

269 As a further test of possible humidity effects, two replicate 24 h CEM filter deployments were
270 conducted in elevated humidity conditions ($10 - 11 \text{ g m}^{-3} \text{ WV}$) created by an in-line water bath.
271 Mean total Hg loading on the primary CEM filters was higher compared to the previous
272 permeations ($11700 \pm 720 \text{ pg}$, $n = 4$, Samples H9-12, Table 1), indicating an increase in the
273 effective HgBr_2 permeation rate, possibly due to the perturbation caused by a poor filter seal and
274 small leak in the preceding deployment (Sample H7-8, Table 1). However, mean total Hg on the

275 secondary CEM filters was 20 ± 20 pg, indicating an average breakthrough of 0.1%, less than the
276 breakthrough observed for the lower humidity permeations.

277 **4 Conclusions**

278 GEM uptake on the CEM material was negligible under the laboratory conditions and high GEM
279 loading rates (2 orders of magnitude above ambient) tested in this study, with an overall linear
280 uptake rate of 0.004% for permeated GEM concentrations between $1.43 \times 10^6 - 1.85 \times 10^6$ pg m⁻³.
281 This uptake rate would be insignificant at typical ambient atmospheric Hg concentrations (1 – 2
282 ng m⁻³). As a hypothetical example, a CEM filter sampling ambient air at an average GEM
283 concentration of 2 ng m⁻³ for a typical 2-week sample period would have a total Hg⁰ exposure of
284 ~40000 pg. At the calculated uptake rate of 0.004%, a maximum 1.6 pg of Hg observed on the
285 sample filter could be attributed to GEM artifact and given that blank filters have a mean total
286 Hg mass of 50 ± 20 pg, this amount would be below detection. This corroborates the lack of
287 GEM uptake seen by Lyman et al. (2016) for manual Hg⁰ injections on CEM filters at lower total
288 mass loadings of 300 – 6000 pg.

289 Mean HgBr₂ breakthrough from primary to secondary CEM filters averaged $0.2 \pm 0.2\%$ over all
290 test conditions, using HgBr₂ as a test GOM compound. A to B filter breakthrough was derived
291 from a comparison between the large amount of HgBr₂ permeated onto the primary CEM filters,
292 to the small amount of HgBr₂ that collected on the secondary CEM filters, 3 mm immediately
293 downstream. The measurement of 1000s of pg of Hg on the primary filter, and only 10s of pg on
294 the secondary filter, leads to the conclusion that the primary filter removed the majority of HgBr₂
295 from the sample air stream. In addition, low breakthrough was corroborated by downstream
296 measurement of the air stream passing through the CEM filters, using the Tekran[®] 2537A. The

297 average breakthrough to the 2537A was 0 pg for 24 h permeations in dry air and 0 – 40 pg in
298 humid air, for those filter deployments than can be considered steady-state (> 24 h without large
299 perturbations).

300 While the permeation system was not specifically optimized for a quantitative mass balance
301 between permeated HgBr₂ and HgBr₂ recovered on the CEM filters, a rough estimation of the
302 CEM collection efficiency is possible. Using the HgBr₂ permeations conducted in clean dry air
303 (mean loading 8560 pg) and comparing this to the mean Hg concentration measured at the
304 2537A analyzer during the last 24 h of the 96 h permeation measurement (4680 pg m⁻³, or 6739
305 pg per 24 h), the HgBr₂ recovery on the CEM filters averaged 127%. Adjusting the expected
306 permeated HgBr₂ mass for our estimated line-loss (~4-5%) improves the recoveries to ~123%.
307 Still, HgBr₂ loading on the CEM filters was therefore ~23% higher than expected based on the
308 pyrolyzed total measurement on the 2537A.

309 The technique of gold amalgamation in general, and specifically including the Tekran[®] 2537
310 analyzer, is widely considered to provide a quantitative *total gaseous Hg* measurement, at or
311 very near 100% collection efficiency for Hg⁰ and Hg compounds (Dumarey et al.,
312 1985; Schroeder and Jackson, 1985; Landis et al., 2002; Temme et al., 2003; Schroeder et al.,
313 1995). However, to our knowledge collection and desorption efficiencies on gold traps have not
314 been demonstrated for HgBr₂. The stated desorption temperature of the Tekran[®] 2537A gold
315 traps is 500 °C, but temperatures as low as 375 °C have been reported (Gustin et al., 2013),
316 which would likely cause reduced thermal decomposition efficiency for all captured GOM
317 compounds, including HgBr₂. We speculate that a combination of incomplete thermal
318 decomposition to Hg⁰, at both the 600 °C pyrolyzer and during the best-case 500 °C desorption

319 of the 2537 gold traps, resulted in ~20% non-detection of total permeated HgBr₂ as it passed
320 through the CVAFS optical path without generating the necessary fluorescence signal.

321 While our results validated some basic performance metrics for the CEM material, they did not
322 provide data that could fully explain the higher levels of breakthrough observed for CEM filters
323 deployed in ambient air over the 1 to 2 week sample periods in previous studies. Increasing
324 humidity by itself did not affect observed HgBr₂ breakthrough. A HgBr₂ loading of ~50000 pg
325 also did not lead to increased breakthrough, indicating there is no saturation effect on CEM filter
326 capacity at a GOM loading far greater than expected from ambient concentrations. It remains
327 unclear, though, whether breakthrough results from different collection efficiencies for GOM
328 compounds other than HgBr₂, or whether breakthrough results from a degradation of GOM
329 retention capacity in the CEM material when exposed to ambient air chemistries not simulated in
330 this study. Also, our experiments were conducted in particulate-free air, which leaves open the
331 possibility that breakthrough is related to capture (or lack thereof) of PBM by the CEM material.

Figure 1. Schematic of the Hg vapor permeation system configurations for: a) GEM permeations b) HgBr₂ permeations c) Simultaneous HgBr₂ loading on two sample lines. Note dry air supplier disconnected for ambient and elevated humidity HgBr₂ permeations, with sample path starting at 0.2 μm Teflon particulate filter and water bath inserted immediately in front of the charcoal scrubber. All tubing is chemically inert PTFE, except for the quartz glass pyrolyzer tube, and PFA filter holders.

433

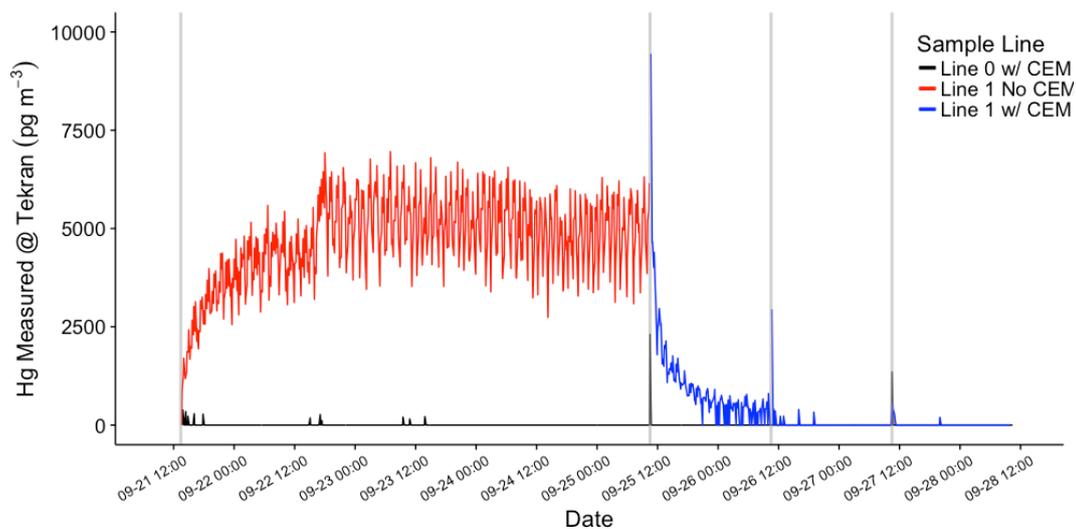

434 **Figure 2.** Total Hg recovered on CEM material for blank filters (Hg exposure = 0 pg) and different Hg⁰ vapor
 435 permeations in dry ($0.5 \pm 0.1 \text{ g m}^{-3} \text{ WV}$) and humid air ($2\text{--}4 \text{ g m}^{-3} \text{ WV}$). Circles represent dry air permeations,
 436 triangles represent humid air exposures, and all permeation exposures were blank-corrected. The regression line
 437 shows the relationship between total Hg⁰ exposure and blank-correct mean total Hg recovered on CEM filters (error
 438 bars \pm one standard deviation), with a slope of 4.1×10^{-5} indicating a linear uptake rate of 0.004%.
