15 16 **Abstract**

17 The first intensive multi-component ground-based remote sensing observations by sky
18 radiometer and Multi-Axis Differential Optical Absorption Spectroscopy (MAX-DOAS) were
19 performed simultaneously at the SKYNET/Phimai site located in central Thailand (15.18°N,
20 102.56°E) from January to April 2016. The period corresponds to the dry season associated
21 with the intense biomass burning (BB) activity around the site. The near-surface concentration
22 of formaldehyde (HCHO) retrieved from MAX-DOAS was found to be a useful tracer for
23 **absorption aerosols from BB plumes, when BB was the dominant sources of HCHO and**
24 **absorption aerosols over other sources.** As the HCHO concentration tripled from 3 to 9 ppbv,
25 the ratio of gaseous glyoxal to HCHO concentrations in daytime decreased from ~0.04 to ~0.03,
26 responding presumably to the increased contribution of volatile organic **compound** emissions
27 from BB. In addition, clear increases in aerosol absorption optical depths (AAODs) retrieved
28 from sky radiometer observations were seen with the HCHO enhancement. At a HCHO of 9
29 ppbv, AAOD at a wavelength of 340 nm reached as high as $\sim 0.15 \pm 0.03$. The wavelength

1 dependence of AAODs at 340-870 nm was quantified by the absorption Ångström exponent
2 (AAE), providing evidence for the presence of brown carbon aerosols at an AAE of 1.5 ± 0.2 .
3 Thus, our multi-component observations around central Thailand are expected to provide
4 unique constraints for understanding physical/chemical/optical properties of BB plumes.

5

6 **1 Introduction**

7 It is well recognized that aerosols contribute the largest uncertainty to the estimate of radiative
8 forcing (*e.g.*, IPCC, 2013). Biomass burning (BB) is a substantial source of aerosols to the
9 atmosphere. Black carbon (BC) is a strongly-light-absorbing component of aerosols and can be
10 emitted in large quantities from BB. In addition, about two-thirds of the global primary organic
11 aerosol (OA) that should comprise a large amount of ultraviolet (UV)-light-absorbing OA,
12 known as brown carbon (BrC), originates from BB plumes (Bond et al., 2013). Currently, most
13 climate models treat OA as purely scattering. Recent laboratory studies suggested that BrC can
14 enhance net absorption by OA, potentially altering the BB direct radiative forcing from negative
15 to positive (Kirchstetter et al., 2004; Saleh et al., 2014). Moreover, underestimation in aerosol
16 absorption over most BB regions was reported by Hammer et al. (2016), who used a global 3-
17 D chemistry transport model (GEOS-Chem), in which OA is regarded as purely scattering. Thus,
18 the potential climate effects of BrC aerosols have received considerable attention recently (*e.g.*,
19 Myhre et al., 2013). In addition, as a result of UV absorption, tropospheric photochemistry can
20 be significantly affected; GEOS-Chem simulation incorporating UV absorption by BrC showed
21 a decrease in tropospheric hydroxyl radical (OH) concentration by up to 15% for BB regions,
22 compared to the simulation without UV absorption by BrC (Hammer et al., 2016). BrC
23 comprises a wide range of poorly characterized compounds that exhibit highly variable
24 absorptivity. Assessing the role of BrC in light absorption is further difficult, because BrC is
25 not only emitted as a primary organic aerosol (POA) but also produced as a secondary organic
26 aerosol (SOA) through complex formation processes from volatile organic compounds (VOCs)
27 originating from BB.

28 This study focuses on the intense BB activity that occurred around central Thailand from
29 January to April 2016. Characterization for the BB plumes is attempted using our unique remote
30 sensing observations by the sky radiometer (*e.g.*, Nakajima et al., 1996) and the Multi-Axis
31 Differential Optical Absorption Spectroscopy (MAX-DOAS) (*e.g.*, Irie et al., 2011) for both
32 viewpoints of the optical properties of aerosols (aerosol absorption optical depth, AAOD and

1 absorption Ångström exponent, AAE) and the organic gas concentrations (formaldehyde,
2 HCHO and glyoxal, CHOCHO) in BB plumes.

3

4 **2 Observation**

5 We conducted ground-based remote sensing observations using the sky radiometer and the
6 MAX-DOAS at the SKYNET/Phimai site (15.18°N, 102.56°E) located in central Thailand from
7 January to April 2016. The period corresponds to the dry season with the occurrence of intense
8 BB around the site. Indeed, satellite data revealed evident enhancements in the carbon
9 monoxide column concentration and the fire radiative power (FRP) around the
10 SKYNET/Phimai site in the dry season (Hoque et al., 2018a, b). Concerning the sky radiometer
11 and the MAX-DOAS, their instrumentation and data analysis/retrieval are described below.

12 **2.1 Sky radiometer observation of aerosol optical properties**

13 The sky radiometer (POM-02; Prede Co., Ltd, Tokyo, Japan), a sun-sky photometer measuring
14 direct and diffuse solar irradiances, is the main instrument of the international ground-based
15 remote sensing network SKYNET (*e.g.*, Takamura and Nakajima, 2004; Nakajima et al., 2007).
16 Measurements of the direct solar and diffuse irradiances within 160° of the center of the Sun
17 were conducted every 10 min. Values of aerosol optical depth (AOD), single scattering albedo
18 (SSA), refractive index at 340, 380, 400, 500, 675, and 870 nm were retrieved using the Sky
19 Radiometer analysis package from Center for Environmental Remote Sensing (SR-CEReS)
20 version 1 (Mok et al., 2018), in which SKYRAD.pack version 5 (Hashimoto et al., 2012) is
21 implemented to retrieve aerosol properties, along with all pre- and post-processing programs
22 for the purpose of the near-real time data delivery. Data at 1020 nm were not used in this study
23 to avoid possible impact by low AAOD and interference by water vapor (H₂O) on the estimate
24 of the AAE. Cloud screening was made by the method of Khatri and Takamura (2009) but
25 without using global irradiance data from a pyranometer.

26 The SKYNET/sky-radiometer has on-site calibration methods, namely the Improved Langley
27 (IL) method **determining** the calibration constant (F_0) (*e.g.*, Campanelli et al., 2007) and the
28 Solar Disk Scan (SDS) method **determining** the solid view angle (SVA) (*e.g.*, Nakajima et al.,
29 1996; Uchiyama et al., 2018). Recently, Mok et al. (2018) used retrievals with SR-CEReS to
30 compare SKYNET/sky-radiometer AOD and SSA data with those derived from a combination
31 of Aerosol Robotic Network (AERONET), Multifilter Rotating Shadowband Radiometer

1 (MFRSR), and Pandora observations in Seoul, Korea during and after NASA KORUS-AQ
 2 (Korea U.S.-Air Quality) campaign in 2016 (Mok et al., 2018 and references therein). For most
 3 cases, their agreements were found to be within ± 0.01 and ± 0.05 for AOD and SSA data,
 4 respectively, at all wavelengths from 340 and 870 nm, supporting the ability of the on-site
 5 calibration methods using IL and SDS.

6 Since the importance of accurate SVA determination was particularly pointed out to better
 7 interpret the difference seen in previous SSA comparisons between SKYNET and AERONET
 8 (Khatri et al., 2016), sensitivity analysis was made in the present study by conducting additional
 9 retrievals using SVAs offset by ± 0.01 msr ($\sim \pm 4\%$), which is likely to correspond to the
 10 uncertainty in SVA determined by a single SDS. Both positive and negative offsets were tested
 11 but only the positive offset is discussed here, because the negative offset tended to show only
 12 little or no impact on SSA, when SSA was close to unity. This is because a smaller SVA leads
 13 to a larger SSA (Hashimoto et al., 2012). The impacts by the SVA offset of $+0.01$ msr on SSAs
 14 were estimated to be as small as -0.010 ± 0.005 , -0.010 ± 0.005 , -0.010 ± 0.005 , -0.010 ± 0.006 , $-$
 15 0.012 ± 0.007 , and -0.011 ± 0.008 at 340, 380, 400, 500, 675, and 870 nm, respectively. Thus,
 16 overestimation (underestimation) in SVA leads to underestimation (overestimation) in SSA,
 17 but the magnitude was found to be very small at about ± 0.01 , when the uncertainty in SVA was
 18 $\sim \pm 0.01$ msr. The small impact on SSAs should be a result of compensation by the associated
 19 change in F_0 values; using SVA values offset by $+0.01$ msr as an input, the IL method employed
 20 in SR-CEReS yields smaller F_0 values by about $2.1 \pm 0.1\%$, $1.8 \pm 0.2\%$, $1.7 \pm 0.2\%$, $1.2 \pm 0.2\%$,
 21 $0.7 \pm 0.2\%$, and $0.5 \pm 0.1\%$ for 340, 380, 400, 500, 675, and 870 nm, respectively. The resulting
 22 smaller F_0 leads to a larger SSA (Hashimoto et al., 2012), which is an opposite trend of the
 23 direct impact that a larger SVA leads to a smaller SSA (Hashimoto et al., 2012). Results from
 24 these sensitivity analyses support the agreement of SSAs within ± 0.05 seen in recent
 25 comparisons by Mok et al. (2018) during and after NASA KORUS-AQ campaign.

26 Using the AOD and SSA data retrieved, AAOD and AAE values were derived as follows. First,
 27 for each measurement and for respective wavelengths from 340 to 870 nm, the AAOD value
 28 and its uncertainty (ε_{AAOD}) were calculated with the following equations:

29

$$30 \quad AAOD(\lambda) = AOD(\lambda) \cdot [1 - SSA(\lambda)] \quad (1)$$

$$31 \quad \varepsilon_{AAOD(\lambda)} = \sqrt{[(1 - SSA(\lambda)) \cdot \varepsilon_{AOD}]^2 + (AOD(\lambda) \cdot \varepsilon_{SSA})^2} \quad (2)$$

1

2 For the estimate of $\varepsilon_{AAOD(\lambda)}$, uncertainties for $AOD(\lambda)$ and $SSA(\lambda)$ (ε_{AOD} and ε_{SSA}) were assumed
3 to be 0.01 and 0.05, respectively, based on comparisons by Mok et al. (2018). Since the
4 comparisons by Mok et al. (2018) were made using independent measurements having
5 uncertainties of the same order of magnitude, the actual uncertainties in sky radiometer AOD
6 and SSA data would be smaller. AAE is calculated as the slope of the linear fit of $\ln[AAOD(\lambda)]$
7 versus $\ln(\lambda)$:

8

$$\ln[AAOD(\lambda)] = a - AAE \cdot \ln(\lambda), \quad (3)$$

10

11 where a is an intercept. This equation is equivalent to expression using the power law:

12

$$AAOD(\lambda) = K\lambda^{-AAE}, \quad (4)$$

14

15 where K is a constant. To exclude AAE data associated with large uncertainty, only the data,
16 which satisfy the criteria that 1) $AAOD(\lambda)$ exceeds $\varepsilon_{AAOD(\lambda)}$ for all wavelengths and 2) the
17 correlation coefficient of the linear fit (R) is high ($-1.0 \leq R \leq -0.9$) are used in the analysis below.

18 To refine the data set of AOD, SSA, AAOD, and AAE with reduced uncertainty, the daily mean
19 and its standard deviation with the number of data more than 4 were calculated for 9:00-15:00
20 LT.

21

22 **2.2 MAX-DOAS observation of trace gases**

23 The MAX-DOAS is an instrument measuring UV-visible spectra of scattered sunlight at several
24 elevation angles between the horizon and zenith (*e.g.*, Hönninger and Platt, 2002; Hönninger et
25 al., 2004; Irie et al., 2015). Its measurement is based on the well-established DOAS technique
26 that quantitatively detects narrow band absorption by trace gases by applying Lambert-Beer
27 law (*e.g.*, Platt and Stutz, 2008). Since the pioneering study by Hönninger and Platt (2002) and
28 Hönninger et al. (2004), various types of instruments and algorithms for MAX-DOAS have
29 been developed worldwide. One of the reasons for this is because ground-based MAX-DOAS

1 observations at a low elevation angle provide enhanced signals of concentrations of important
2 trace gases in the boundary layer (*i.e.*, around the instrument altitude) and the concentrations
3 can be interpreted as being the average over a distance, which is on the same order of or finer
4 than the horizontal resolution of models and satellite observations but coarser than that of in situ
5 observations (Irie et al., 2011).

6 From January to April 2016, our MAX-DOAS system (PREDE, Co., Ltd) (Irie et al., 2011;
7 Hoque et al., 2018a, b) was operated continuously at the SKYNET/Phimai site together with
8 the sky radiometer. It was combined with the spectrometer Maya2000Pro (Ocean Optics, Inc.)
9 (with a slit of 25 μm) embedded in a temperature-controlled box to record high-resolution
10 spectra (with the full width at half maximum of around 0.3-0.4 nm and the oversampling of 3-
11 4) from 310 to 515 nm. Measurements were made at six elevation angles of 2°, 3°, 4°, 6°, 8°,
12 and 70° every 30 min. Instead of 90°, the 70° elevation angle was adopted as reference to reduce
13 a variation range of signals measured at all the elevation angles, while the integration time was
14 kept constant. MAX-DOAS off-axis elevation angle measurements were limited to below 10°
15 for minimizing the possible systematic error in oxygen collision complex fitting results but
16 keeping the measurement sensitivity in the lowest layer of vertical profiles retrieved high (Irie
17 et al., 2015).

18 Spectral analysis by the so-called DOAS method (Platt and Stutz, 2008) for spectral fitting
19 using the nonlinear least-squares method and the subsequent vertical profile retrievals using the
20 optimal estimation method were performed by our retrieval algorithm, JM2 (Japanese MAX-
21 DOAS profile retrieval algorithm, version 2) (*e.g.*, Irie et al., 2008; Irie et al., 2011; Irie et al.,
22 2015). Using the recorded high-resolution UV-visible spectra from 310 to 515 nm, the JM2
23 allows us to retrieve lower-tropospheric vertical profile information for 8 quantities, including
24 HCHO, CHOCHO, nitrogen dioxide (NO_2), and H_2O concentrations, which are analyzed below.
25 We used fitting windows and cross section data identical to those described by Irie et al. (2011,
26 2015) and Hoque et al. (2018a). The residual for DOAS fitting was usually as low as below 10^{-3} .
27 In the vertical profile retrieval, the elevation angle setting was fully considered in the
28 computation of differential air mass factors (*e.g.*, Irie et al., 2011, 2015). The input parameters
29 used for the vertical profile retrievals are the same as those used by Irie et al. (2015) for Cabauw,
30 the Netherlands. The degrees of freedom for signal for trace gas vertical profiles retrieved here
31 were usually 1-2. Of vertical profiles retrieved, the present study analyzed data for a layer of 0-
32 1 km, which corresponds to the lowest layer with the highest sensitivity owing to the longest

1 light path in profiles retrieved by JM2. The total uncertainties, including random and systematic
2 errors, were estimated to be 24% (HCHO), 19% (CHOCHO), 15% (NO₂), and 18% (H₂O) (Irie
3 et al., 2011). For HCHO (CHOCHO, NO₂, and H₂O) retrievals, the systematic error was
4 estimated by conducting additional retrievals as JM2 aerosol retrieval uncertainties of 50%
5 (30%), in which uncertainty due to assuming fixed SSA values should be included (Irie et al.,
6 2008; Irie et al., 2011; Hoque et al., 2018a, b). Using the retrieved H₂O concentration, the
7 relative humidity over water (RH_w) for the layer 0-1 km was estimated using NCEP (National
8 Centers for Environmental Prediction) pressure and temperature reanalysis data (2.5-degree
9 grid and 6-hourly). To be consistent with sky radiometer data, the daily mean values for 9:00-
10 15:00 LT are analyzed in this study. More detailed descriptions about MAX-DOAS, including
11 fitting windows and cross section data, are given by Irie et al. (2011, 2015), Hoque et al. (2018a,
12 b), and references therein.

13

14 **3 Results and Discussion**

15 Time series of multi-components retrieved from sky radiometer and MAX-DOAS observations
16 at the SKYNET/Phimai site for the intense biomass burning period from January to April 2016
17 is shown in Fig. 1. As seen in Fig. 1, RH_w for a layer of 0-1 km derived from MAX-DOAS
18 observations and the surface RH_w from NCEP data confirm that the period was dry around
19 Phimai, particularly from the beginning of February through the middle of April (from days 32
20 to 110). For the period of January-April 2016, mean AOD values at 340, 500, and 865 nm were
21 high at 0.98±0.41, 0.64±0.27, and 0.27±0.11, respectively. The AOD values reached the peak
22 in late March (around days 80-85), when AAOD values and HCHO, CHOCHO, and NO₂
23 concentrations were synchronously high. From Fig. 1, positive correlations among them are
24 suggested.

25 In Fig. 2, CHOCHO concentrations, ratios of CHOCHO to HCHO concentrations (R_{GF}), NO₂
26 concentrations, and AAOD values are plotted against the HCHO concentration. The R_{GF} is
27 important for atmospheric chemistry as it would vary responding to different VOC emissions
28 such as BB and biogenic activities (e.g., Hoque et al., 2018a, b). HCHO was chosen as a
29 standard, since its lifetime was likely comparable to or longer than the other two potential BB-
30 originating trace gases investigated here (i.e., CHOCHO, and NO₂) (e.g., Li et al., 2013) and
31 its variation range was larger than the other two (Figs. 1 and 2). We found moderate tight
32 correlations between CHOCHO and HCHO concentrations (a determination coefficient R^2 of

1 **~0.5 for linear fit**). As the HCHO concentration tripled from 3 to 9 ppbv, the R_{GF} decreased
2 from ~ 0.04 to ~ 0.03 and the NO_2 concentration doubled from ~ 0.6 to ~ 1.2 ppbv, responding
3 presumably to the increased contribution of VOC emissions from BB. The R_{GF} values are
4 slightly greater than those reported by Hoque et al. (2018a, b), whose statistics included data
5 taken in early morning and late evening, when R_{GF} values were tended to be low compared to
6 mid-day values analyzed in the present study. At a HCHO concentration of 9 ppbv, AAOD at
7 340 nm reached as high as $\sim 0.15 \pm 0.03$. Much larger AAODs were seen at a HCHO
8 concentration higher than 9 ppbv (Fig. 2). These results provide strong observational evidence
9 that aerosols in BB plumes (*i.e.*, POA and SOA) **absorb UV radiation significantly**. In addition,
10 Fig. 2 reveals that HCHO is a good tracer for absorption aerosols from BB, **reflecting that BB**
11 **caused clear enhancements of both HCHO and absorption aerosols, when BB was the dominant**
12 **sources of HCHO and absorption aerosols over other sources.**

13 While BC has been shown to have an AAE of about unity in literature, AAE values greater than
14 unity are interpreted as BrC (*e.g.*, Kirchstetter et al., 2004). For the whole period from January
15 to April 2016, the mean AAE was estimated to be 1.57 ± 0.28 for the entire wavelength region
16 from 340 to 870 nm (Fig. 3). Only for a shorter-wavelength range from 340 to 500 nm, the
17 mean AAE was estimated to be 1.93 ± 0.59 (Fig. 3). A larger AAE for a shorter-wavelength
18 range was also reported by Chakrabarty et al. (2010) for BrC in tar balls from smoldering
19 biomass combustion. Also shown in Fig. 3 are data of the imaginary part of refractive index (k)
20 retrieved from sky radiometer observations, indicating a strong wavelength-dependence. The
21 wavelength-dependence was quantified similarly to Eq. (3) as the slope (w) of the linear fit of
22 $\ln(k)$ versus $\ln(\lambda)$. The k values in the UV region were as high as 0.01-0.03 but one order of
23 magnitude smaller than that of BC (~ 0.71) (Bond and Bergstrom, 2005). Using the
24 parameterization derived by Saleh et al. (2014) and the k value at 550 nm (k_{550}) derived by
25 interpolation in the present study (~ 0.012), the BC-to-OA ratio of the emissions from BB
26 ($R_{BC/OA}$) around Phimai was estimated to be 1.9%. A $R_{BC/OA}$ ratio less than 1.9% is suggested
27 for smoldering combustion of duffs investigated by Chakrabarty et al. (2010) as their k_{550} value
28 is smaller than that estimated for Phimai in the present study.

29 Since HCHO is a good tracer for absorption aerosols from BB as mentioned above, it is
30 interesting to investigate the dependence of AAE on the HCHO concentration. We found,
31 however, that their correlations were weak and the AAE at a HCHO of 3 ppbv (~ 1.7) tended to
32 be higher than the AAE values at higher HCHO concentrations (~ 1.5) (Fig. 4). Although

1 uncertainty in the estimate for the single data of daily mean AAE was as large as 0.3-0.5, it can
2 be seen that AAE tended to converge to 1.5 ± 0.2 at a higher HCHO concentration in BB plumes.
3 According to smog chamber experiments by Saleh et al. (2014), aerosol absorptivity depends
4 largely on burn conditions, not fuel type. In addition, the size distribution and the mixing state
5 of BC and OA can be important factors for AAE (e.g., Russel et al., 2010; Kirchstetter et al.,
6 2004). It was also reported that non-absorbing shells over BC cores can lead to AAE greater or
7 less than unity (Gyawali et al., 2009). Despite such a complexity in interpretation of the
8 variation in AAE and the uncertainty in sky-radiometer-retrieved AAE as large as 0.3-0.5, we
9 attempted to interpret possible enhancement in AAE at a HCHO of 3 ppbv. For this, using the
10 parameterization of Salah et al. (2014) and the k_{550} values, the $R_{BC/OA}$ ratio for a low HCHO
11 case at 3 ppbv was calculated to be 0.013, which was smaller than the $R_{BC/OA}$ ratios at higher
12 HCHO concentrations (e.g., 0.023 at a HCHO of 9 ppbv) (Fig. 4). A smaller $R_{BC/OA}$ ratio can
13 be attributed to the lower-temperature BB. In this case, the lower-temperature BB could yield
14 only small values of AOD, AAOD, HCHO, and CHOCHO (i.e., the magnitude of BB emissions
15 was weak) but a high value of AAE about 1.7 (i.e., as a results of a smaller $R_{BC/OA}$ ratio for
16 emissions) (Fig. 4). The other interpretation for the enhancement in AAE at a HCHO of 3 ppbv
17 is that we observed more photochemically-aged BB plumes at smaller HCHO concentrations.
18 As the photochemical aging occurred, more SOA should have been produced, leading to
19 stronger wavelength-dependence of absorption. Considering a large uncertainty in AAE data
20 used here, further investigation using more data from our multi-component observations by sky
21 radiometer and MAX-DOAS is encouraged to better interpret the characteristics of BB plumes
22 observed in this study. In addition, the results presented here are expected to be unique
23 constraints for understanding physical/chemical/optical properties of BB plumes.

24

25 **4 Conclusions**

26 We conducted ground-based remote sensing observations using the sky radiometer and the
27 MAX-DOAS at SKYNET/Phimai site in central Thailand from January to April 2016 to
28 characterize optical properties of aerosols and organic gas concentrations in BB plumes. We
29 found that the HCHO concentration for a layer of 0-1 km retrieved from MAX-DOAS was a
30 useful tracer for **absorption aerosols from BB plumes, when BB was the dominant sources of**
31 **HCHO and absorption aerosols over other sources**. As the HCHO concentration tripled from 3
32 to 9 ppbv, the R_{GF} decreased from ~ 0.04 to ~ 0.03 , in respond presumably to the increased

1 contribution of VOC emissions from BB. In addition, AAODs increased with HCHO. At a
2 HCHO of 9 ppbv, AAOD at 340 nm reached as high as $\sim 0.15 \pm 0.03$. The AAE at 340-870 nm
3 was about 1.5 ± 0.2 , indicating the presence of BrC aerosols. The results from our multi-
4 component observations around central Thailand are expected to be unique constraints for
5 understanding physical/chemical/optical properties of BB plumes.

3 Fig. 1. Time series of multi-components retrieved from sky radiometer and MAX-DOAS
 4 observations at Phimai, Thailand for the intense BB period from January to April 2016. Daily
 5 means for 9:00-15:00 LT are plotted. Their 1σ standard deviations are shown by error bars.
 6 AOD, SSA, and AAOD values for different wavelengths are shown in different colors. For RH_w ,
 7 red symbols indicate MAX-DOAS-derived RH_w for a layer of 0-1 km and black symbols
 8 indicate the surface RH_w from NCEP data.

9

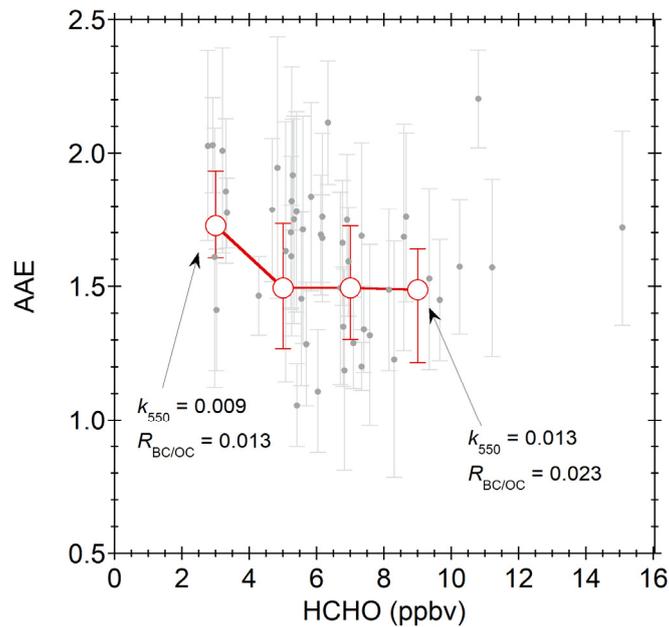

1
 2 Fig. 2. (a) CHOCHO concentration, (b) R_{GF} , (c) NO_2 concentration, and (d) AAOD values
 3 plotted as a function of HCHO concentration. AAOD values at 340, 400, and 870 nm are shown
 4 in blue, green, and black, respectively. The medians of respective quantities for each 2-ppbv
 5 bin of HCHO concentration are shown by open symbols. Error bars represent 67%-ranges.
