Abstract. An incoherent broadband cavity-enhanced absorption spectrometer (IBBCEAS) instrument for quantification of atmospheric trace gases that absorb in the cyan region of the electromagnetic spectrum (470 to 540 nm), including NO2 and I2, is described. The instrument uses a light-emitting diode coupled to a 1 m optical cavity consisting of a pair of mirrors in stable resonator configuration. Transmitted light is monitored using a grating spectrometer and charge-coupled device array detector. The average mirror reflectivity was determined from the N2/He and Ar/He ratios of scattering coefficients and was ~99.98% at its maximum, yielding an effective optical path length of 6.3 km. Cross-sections of N2, O2, air, Ar, CO2, and CH4 scattering and of O4 absorption were measured and agree with literature values within the measurement uncertainty. Trace gas mixing ratios were retrieved using the spectral fitting software DOASIS from 480 to 535 nm. Under laboratory conditions, the 60 s, 1σ measurement precisions were ±124 and ±44 pptv for NO2 and I2, respectively. The IBBCEAS instrument sampled ambient air in Ucluelet, BC, in July 2015. IBBCEAS retrievals agreed with independent measurements of NO2 by blue diode laser cavity ring-down spectroscopy (r2 = 0.975), but ambient I2 concentrations were below the detection limit.

1 Introduction

Cavity-enhanced absorption spectroscopy (CEAS) has emerged in recent years as a sensitive technique for direct measurement of atmospheric trace gases (Fiedler et al., 2003; Gherman et al., 2008; Vaughan et al., 2008; Washenfelder et al., 2008; Schuster et al., 2009; Thalman and Volkamer, 2010; Hoch et al., 2014) and of aerosol optical extinction (Thalman and Volkamer, 2010; Bluvshtein et al., 2012; Washenfelder et al., 2013). Similar to other cavity-enhanced techniques (Gagliardi and Loock, 2014), CEAS owes its high sensitivity to highly reflective mirrors (reflectivity, R > 99.9%) which yield long effective absorption path lengths. In CEAS, light generated from a high intensity broad-band light source (e.g., a Xe arc lamp) is transmitted through an optical cavity set up in a stable resonator configuration. The output spectrum is integrated yielding extinction spectra from which mixing ratios are retrieved using known absorption spectra and knowledge of the mirror reflectivity and effective optical absorption path (Meinen et al., 2010). To date, CEAS instruments have been used to quantify mixing ratios of many
atmospherically important trace gases, including nitrogen dioxide (NO2) (Langridge et al., 2008; Gherman et al., 2008; Triki et al., 2008; Thalman and Volkamer, 2010; Wu et al., 2014; Min et al., 2016; Varma et al., 2009), the nitrate radical (NO3) (Langridge et al., 2008; Schuster et al., 2009; Venables et al., 2006; Varma et al., 2009), iodine (I2) (Ball et al., 2010; Dixneuf et al., 2009; Bahrini et al., 2018), the iodine oxides IO and OIO (Vaughan et al., 2008), glyoxal (HCOHCO) (Washenfelder et al., 2008; Thalman and Volkamer, 2010; Coburn et al., 2014; Min et al., 2016), methyl glyoxal (CH3COCHO) (Thalman and Volkamer, 2010; Thalman et al., 2015; Min et al., 2016), molecular bromine (Br2), bromine monoxide (BrO) (Chen and Venables, 2011; Hoch et al., 2014), formaldehyde (Washenfelder et al., 2008; Thalman and Volkamer, 2010), and nitrous acid (HONO) (Gherman et al., 2008; Wu et al., 2014; Min et al., 2016).

The accuracy of retrievals depends on knowledge of relevant absorption and scattering (i.e., Rayleigh) cross-sections (which both contribute to the optical extinction) and of the mirror reflectivity. Because of its high sensitivity, CEAS in turn has been utilized to measure these parameters. For example, Axson et al. and Kahan et al. recently reported the absorption cross-sections of O3 and H2O2 (Axson et al., 2011; Kahan et al., 2012), and Thalman and Volkamer reported scattering cross-sections of N2, O2, Ar, and air (Thalman and Volkamer, 2010) for several wavelength intervals (345 – 390, 435 – 490, 515 – 545, 560 – 600, and 600 – 700 nm).

In spite of the large number of CEAS instruments that have been constructed, the mid-visible region has received relatively little attention to date, other than the pioneering study by Vaughan et al. (2008), even though the absorption maxima of several key atmospheric traces gases, such as NO2 and the iodine species I2, IO and OIO, are located in this wavelength interval (Figure 1). The study of iodine chemistry has been of considerable interest due to potential effects on the formation of new particles and atmospheric oxidising capacity through, for example, catalytic destruction of O3, altering the partitioning of NOx (= NO + NO2) and HOx (= HO + HO2), or the activation of chlorine and bromine from sea salt aerosol in the marine and polar boundary layer, near salt lakes and volcanoes, and in the stratosphere (Saiz-Lopez et al., 2012). Prior laboratory measurements by Vaughan et al. used a 150 W Xenon arc lamp; such light sources tend to flicker, i.e., exhibit intensity fluctuations, which add noise to the absorption spectrum. For this and other reasons (such as compactness, heat generation, etc.), light-emitting diodes (LEDs) are now commonly used to generate broad-band radiation (Washenfelder et al., 2008; Min et al., 2016).

In this paper, we describe an LED-powered incoherent broadband cavity-enhanced absorption spectroscopy (IBBCEAS) instrument operated in the cyan region of the electromagnetic spectrum. We report laboratory measurements of scattering cross-sections for N2, O2, Ar, CO2, CH4 and air from 480 to 535 nm and demonstrate detection of NO2 and I2 in laboratory-generated air. The IBBCEAS instrument was operated during the Ozone-depleting Reactions in a Coastal Atmosphere (ORCA) field campaign, conducted July 8-31, 2015 at the Amphitrite Point Observatory (APO) in Ucluelet on the west coast of Vancouver Island, British Columbia (Tokarek et al., 2017).

Kelp forests are present along this coast line (Watson and Estes, 2011), which are expected to emit I2 (Dixneuf et al., 2009; Nitschke et al., 2015; Nitschke et al., 2011). Mixing ratios of NO2 retrieved from the cyan IBBCEAS data are compared to those measured by a co-located blue diode laser cavity ring-down spectrometer. The potential of the instrument for quantification of iodine species in laboratory and field experiments is assessed.

2 Theory
2.1 Cavity-enhanced spectroscopy

The principle of broadband trace gas measurements by IBBCEAS has been described elsewhere (Fiedler et al., 2003; Washenfelder et al., 2008). Briefly, broadband radiation is continuously injected and trapped between a set of highly reflective mirrors forming a stable resonant cavity. The integrated cavity output intensity represents the combined extinction by the mirrors and the intra cavity medium. The absorption coefficient, $\alpha_{abs}(\lambda)$, is given in terms of the transmission signal through the cavity (Washenfelder et al., 2008) by Eq. (1):

$$\alpha_{abs}(\lambda) = R_L \left( \frac{1 - R(\lambda)}{d} + \alpha_{Ray}(\lambda) \right) \left( \frac{I_0(\lambda) - I(\lambda)}{I(\lambda)} \right)$$

Here, $R_L$ (see Sect. 3.3) is the ratio of the cell length ($d \approx 102$ cm) divided by the length occupied by the sample ($d_0 \approx 82$ cm - section 3.3), $R(\lambda)$ is the average wavelength dependent mirror reflectivity, $d$ is the distance between the two reflective surfaces (i.e. the cavity length), $\alpha_{Ray}(\lambda)$ is the sum of all Rayleigh scattering sample constituents, $I_0(\lambda)$ is the intensity spectrum in the absence of absorbers in the cavity cell, and $I(\lambda)$ is the intensity spectrum measured in the presence of absorbers. When measurements are carried out in variable pressure environments (e.g., aircraft altitude change), an additional term ($\Delta \alpha_{Ray}(\lambda)$) is added to Eq. (1) to account for pressure fluctuations (Min et al., 2016). If multiple absorbers are present in the cavity, the absorption coefficient becomes the sum of all species expressed as in Eq. (2) (Washenfelder et al., 2008).

$$\alpha_{abs} = \sum_i^n \alpha_i(\lambda) = \sum_i^n N_i \sigma_i(\lambda, T, p)$$

Here, $\sigma(\lambda, T, p)$ is the wavelength, temperature, and pressure-dependent absorption cross-section, and $N_i$ is the number density of the $i^{th}$ absorbing gas.

2.3 Determination of Rayleigh scattering cross-sections

Cavity-enhanced spectroscopic techniques allow accurate and precise measurements of Rayleigh scattering cross-sections of pure gases over broad wavelength regions (Naus and Ubachs, 2000; Sneep and Ubachs, 2005; Axson et al., 2011; Kahan et al., 2012; Thalman et al., 2014). If the mirror reflectivity $R(\lambda)$ is known, the scattering cross-section of any gas can be determined by measuring its extinction and that of a reference gas (Thalman et al., 2014), e.g., for CO2 and using He as a reference:

$$\alpha_{Ray}^{CO2}(\lambda) = \left( \frac{1 - R(\lambda)}{d} \left( 1 - \frac{I_{CO2}(\lambda)}{I_{He}(\lambda)} \right) \right) + \alpha_{Ray}^{He}(\lambda) \left( \frac{I_{He}(\lambda)}{I_{CO2}(\lambda)} \right)$$

Here, $\alpha_{Ray}(\lambda)$ is the optical extinction (in cm$^{-1}$) caused by the intra-cavity scattering medium. The scattering cross-sections are then calculated through division by the number density of the gas ($N_{gas}$), i.e.,

$$\sigma_{Ray}(\lambda) = \frac{\alpha_{Ray}(\lambda)}{N_{gas}}$$

Scattering cross-sections can be predicted if the refractive index, $n$, of a gas is known (Naus and Ubachs, 2000; Sneep and Ubachs, 2005), hereafter referred to as an "$n$-based" cross-section, $\sigma_n$.
\[ \sigma_n(\nu) = \frac{24\pi^3\nu^4}{N^2} \left( \frac{n^2(\nu) - 1}{n^2(\nu) + 1} \right)^2 F_k(\nu) \]  

Here, \( \nu \) is the frequency in wavenumbers (cm\(^{-1} \)), \( n(\nu) \) is the frequency dependent refractive index of the gas, and \( F_k \) is the King depolarization ratio which describes the effect of molecular anisotropy (King, 1923).

3 Experimental

3.1 Description of the IBBCEAS instrument

The IBBCEAS instrument consists of an LED light source, collimating optics, a high finesse optical cavity, focusing optics, specialized fibre bundle, and a spectrograph equipped with a charge-coupled device (CCD) camera (Figure 2). The optical cavity consists of two dielectric-coated, plano-concave fused silica substrate mirrors (Advanced Thin Films, Boulder, CO, USA) with maximum reflectivity from 460 to 550 nm, 2.54 cm in diameter, 0.635 cm thickness, and 1 m radius of curvature. To span a broad wavelength range, the mirrors were coated with two highly reflective substrates, resulting in a double maximum in their reflectivity. The mirrors were mounted on both ends of a 102 cm long cell with a gas sampling region of \( \approx 73 \) cm and housed in a custom-built mount equipped with purge gas ports. A flow of 50 standard cubic centimeters per minute (sccm) of ultrapure air (“zero” grade, Praxair) set using 50 \( \mu \)m critical orifices (Lenox Laser, Glen Arm, MD, USA) and a gas regulator back pressure of 138 kPa was directed to each mirror to protect the optical surfaces from contamination. The mirror mounts were attached to adjustable kinematic mounts (Newport U200-A, Irvine, CA, USA) each equipped with 3 set screws for mirror alignment. The gas sampling region was enclosed using 1.9 cm outer diameter (o.d.) and 1.59 cm inner diameter (i.d.) fluorinated ethylene propylene (FEP) Teflon™ tubing (Saint Gobain Plastics, Chemfluor series). The Teflon™ tube was held in place by a custom enclosure constructed from Aluminium. Gases entered and exited the sampling region through 1.9 cm o.d. perfluoroalkoxy alkane (PFA) Teflon™ fittings (Entegris Fluid Handling, Billerica, MA, USA).

The LED (Thorlabs M505L3, Newton, NJ, USA; 400 mW nominal output power) output was collimated into the cavity by a single f/0.8 aspheric condenser lens (Thorlabs ACL2520U-A). The cavity output was collected and focused by a 2.5 cm diameter f/1 lens through a non-polarizing quartz beam splitter (Thorlabs BS025) onto a 0.5 cm (diameter) f/4 fibre adapter that couples the radiation into a 2 m long 0.22 numerical aperture (NA) fibre bundle (Thorlabs BFL200HS02). The beam splitter has 90% transmission efficiency in the plane parallel to the cavity and 10% in the orthogonal plane and was used to direct the emission lines of a Hg(Ne) spectral calibration lamp (Newport Oriel 6032) towards the detector for calibration of the spectrometer wavelength scale and line width. The fibre bundle consists of \( 7 \times 200 \) \( \mu \)m optical fibres arranged with circular and linear configurations on the input and output, respectively. The fibre bundle output was oriented linearly along the spectrograph entrance slit to optimize coupling of the cavity output similar to (Min et al., 2016; Washenfelder et al., 2016), and illuminated the full vertical dimension of the CCD. Spectra were acquired by a 150 cm focal length f/4 dual grating Czerny-Turner spectrograph (Princeton Instruments Acton SP2156, Trenton, NJ, USA) which back-illuminates a 16-bit 1340 \( \times \) 100 pixel CCD array (Princeton Instruments, PIXIS 100B), mounted at the focal plane of the spectrograph and Peltier-cooled to -80 °C to reduce thermal noise. The spectrograph was configured with a 1200 groove mm\(^{-1} \) grating blazed at 500 nm. This configuration along with the
A grating positioned at 500 nm central wavelength yielded spectral coverage from 446.9 to 563.2 nm spanning a total of 1340 discrete wavelength points. The Acton SP2156 spectrograph shipped with a mechanical shutter, which was removed in lieu of software control of the integration time via LABVIEW™ (National Instruments, Austin TX, USA). A fixed entrance slit width of 50 μm yielded approximately Gaussian profiles of the atomic Hg emission lines with full-width at half maximum (FWHM) of (0.330±0.003) nm at 540.06 nm. Other spectral lines (e.g., 520.39 nm) showed slightly lower resolution of roughly (0.360±0.016) nm (Figure S1). An integration time of 5-6 s saturated the CCD pixels 80–90% of their well depth near 500 nm.

All mechanical and optical components were mounted on an optical breadboard (Thorlabs MB2448) bolted onto aluminium structural rails (80/20, Columbia City, IN, USA). The net weight of the instrument including the breadboard and railing is < 90 kg and the overall power consumption below 300 W.

The IBBCEAS instrument samples air through a 47 mm diameter, circular, permeable polytetrafluoroethylene (PTFE) Teflon™ membrane filter with 1 μm pore size (Pall Teflon™ Series, Port Washington, NY, USA) housed in a PFA Teflon™ filter holder (Cole-Parmer R-06621-40) and through 0.635 cm outer diameter and 0.476 cm FEP Teflon™ tubing. The sample flow was set using a mass flow controller (MFC, MKS Instruments 100 B series, 15 standard litres per minute (slpm) capacity, Andover, MA, USA) connected to a diaphragm pump (KNF Neuberger UNO26.1.2ATP, Trenton, NJ, USA). The sample flow was in the range 1.5–2.5 slpm resulting in a sample residence time of 5.9–3.5 s. The gas temperature was measured using a K-type thermocouple (Omega, Laval, QC, Canada) attached to the aluminium sample cell enclosure. Pressure was measured using a pressure transducer (MKS Baratron capacitance manometer 722B) mounted on the exhaust portion of the IBBCEAS between the gas sample cell and the MFC.

The light source is a small footprint (1×1 mm) broadband LED (M505L3, Thorlabs) mounted on the end of a heat sink supplied by the manufacturer. We modified this assembly by mounting a Peltier module (CUI Inc. CP30238, Tualatin, Oregon, USA) between the LED and the heat sink for temperature control using a proportional–integral–derivative (PID) controller (Omega CNi3253) to 30.0±0.1 °C. If not stabilized, the LED output red-shifted ~0.1 nm per °C temperature change. The LED was operated just below the maximum current of 1000 mA (3.3 W of electrical power).

The LED output spectrum was characterized by an asymmetric shape, an emission maximum at 507.5 nm, and a peak width of 22.5 nm FWHM, and was a good match with the mirror reflectivity curve (Figure 3).

### 3.2 Determination of the mirror reflectivity

The response of the IBBCEAS instrument depends on $R(\lambda)$ and $d_0$ (Eq. (1)), which need to be accurately known. If an optical cavity is filled with a non-absorbing and inert gas, and aerosol are removed by filtering, the optical extinction is due to gas scattering only. In this case, $R(\lambda)$ can be derived from the extinction caused by two individual gases with known and different scattering cross-sections such as N₂ and He (Washenfelder et al., 2008):

$$R(\lambda) = 1 - d \frac{N_2}{H_2} \frac{\epsilon_{Ray}^{N_2}(\lambda) \epsilon_{Ray}^{He}(\lambda)}{\epsilon_{Ray}^{H_2}(\lambda)}$$  (6)
Here, $I_X(\lambda)$ and $\alpha_{\text{Ray}}^X(\lambda)$ are the intensities and extinction coefficients of N$_2$ and He, respectively. Other pairs (e.g., He and Ar) may be used as well. For this work, we chose scattering cross-sections from (Peck and Khanna, 1966) for N$_2$, (Cuthbertson and Cuthbertson, 1932) for He, and (Peck and Fisher, 1964) for Ar. Typically, combinations with He provide a higher signal-to-noise due to He having a much smaller scattering cross-section than other gases (Thalman et al., 2014). The above approach assumes that scattering and absorption within the optical cavity are small (Washenfelder et al., 2008) and neglects absorption and scattering due to the mirror substrate.

To determine $R(\lambda)$ in this work, the cavity output intensity was recorded when the cell was filled with high purity N$_2$ (99.998%) or with He (99.998%) to atmospheric pressure (~890 hPa). In each case, the gases were delivered from a compressed gas cylinder (Praxair) and continuously injected through the purge ports until all other sample cell constituents were displaced through the open inlet port. To corroborate the results, the cavity was also filled with Ar (99.998%), which has slightly larger scattering cross-sections than other gases (Thalman et al., 2014).

Figure 3a shows cavity-enhanced transmission spectra with the optical cavity filled with N$_2$, He, and Ar, each averaged over a 15 min time period. The intensity difference due to scattering by Ar and N$_2$ was more pronounced in the case when the sample cell was filled with He (Figure 3a, inset), as expected based on their relative cross-sections (Thalman et al., 2014).

Figure 3b shows the reflectivity spectra calculated using Eq. (6). The reflectivity curves are essentially smooth continua, with maximum reflectivity of ~99.98%. The relative difference between the reflectivity calculated from the ratios of Ar/He and N$_2$/He was < 1.6×10$^{-6}$ in the 480–530 nm range. Arbitrarily, the N$_2$/He mirror curve was chosen to calculate the mirror reflectivity for the remaining data analysis in this work with the exception of the scattering cross-sections of N$_2$ and CO$_2$ (see Sect. 4.1.1 and 4.1.5) for which the Ar/He pair was used. The observed reflectivity corresponds to a total path length ($d/(1-R)$) of 5.5 and 6.3 km near 485 nm and 520 nm, respectively. Intermittent measurements of mirror reflectivity showed that it remained unchanged throughout this work; in particular, no difference in reflectivity was found prior to and following the ORCA campaign.

The overall uncertainty in the measured mirror reflectivity was ±2.3%, resulting from addition by quadrature of a ±1% uncertainty in the N$_2$ scattering cross-section (Peck and Khanna, 1966), a ±2% uncertainty in the He cross-section (Washenfelder et al., 2008; Min et al., 2016), ±0.4% uncertainty in temperature, ±0.1% uncertainty in pressure, and ±0.1% random noise due to photon counting statistics.

3.3 Determination of the effective optical absorption path

When sampling ambient air, knowledge of the path length over which sampled air is present ($d_0$) and the associated correction factor $R_L$ is essential for accurate IBCEAS measurements when purge gases are used to maintain clean mirrors as in this work. The effective cavity length, $d_0$, was determined by sampling pure oxygen and monitoring the O$_2$ dimer (Duan et al., 2018). This experiment was performed in the 350 - 390 nm wavelength region using highly reflective mirrors and an LED (Thorlabs M365LP1) suitable for this wavelength region, though in principle it could have been performed in the cyan region as well since both spectral regions contain O$_2$ absorption lines. Following Duan et al. (2018), $d_0$ is given by
\[ d_0 = d \times \frac{[O_2]_{lon}}{[O_2]_{off}} \]  

where \([O_2]_{lon}\) and \([O_2]_{off}\) are the \([O_2]\) retrieved using cross-sections by (Thalman and Volkamer, 2013) with or without the purge flows. Consistent results were obtained when a constant mixing ratio of NO\(_2\) was sampled (and purge flows were turned on and off) and from the ratio of expected absorption by O\(_4\) (calculated from the square of the number density of O\(_2\) and the O\(_4\) cross-section) relative to the observed O\(_4\) absorption, though the latter may be less accurate as the absorption changes non-linearly in the region where purge and sample gases mix and requires accurate knowledge of mirror reflectivity.

At a sample flow rate of 2.0 slpm, a purge flow rate of 0.1 slpm, and cell pressure of 870 hPa, we determined \(R_L = \frac{d}{d_0} = 1.28 \pm 0.05\) (1\(\sigma\) precision stated) with an accuracy of \(\pm 5\%\). This \(R_L\) value is smaller than calculated from the ratio of the inter-mirror distance \(d\) to the distance between the inlet and outlet of the sample flow (~1.39), which suggests that sampled air partially mixes into the purge volume. At a volumetric flow rate of 11 liters per minute as deployed during ORCA, we observed \(R_L = 1.20 \pm 0.07\) (1\(\sigma\) precision).

### 3.4 Reference absorption cross-sections

Figure 1 shows trace absorbers in the 480–530 nm window calculated as extinction \((\alpha(\lambda) = \sigma(\lambda)N)\) for typical atmospheric mixing ratios. CEAS analysis was performed using the high-resolution NO\(_2\) absorption cross-section of Voigt et al. (2002) and the cross-sections of Spietz et al. for OIO (Spietz et al., 2005) and I\(_2\) (Spietz et al., 2006), respectively. The NO\(_2\) cross-section was convolved with the instrument function corresponding to a sharp peak line (540.06 nm) in the emission spectrum of the Hg(Ne) calibration lamp (Figure S2), which was also used to calibrate the wavelength scale of the spectrometer.

The IBBCEAS instrument's resolution was 0.33 nm in the 480–530 nm window, whereas the NO\(_2\) literature spectrum was recorded at a higher resolution of better than 0.005 nm (Voigt et al., 2002). A convolved NO\(_2\) reference spectrum was used for the least-squares analysis. The literature cross-sections of I\(_2\) and OIO (Spietz et al., 2005; 2006) at a resolution of 0.59 nm were not convolved because their resolution was lower than that of the IBBCEAS instrument. The NO\(_2\) absorption cross-section is somewhat pressure-dependent, which is important considering that the IBBCEAS instrument was operated at ~466 hPa in the field. Voigt et al. (2002) reported cross-sections at 1333 and 133 hPa (in N\(_2\)). Following convolution to the IBBCEAS instrument, these differences were judged to be small (2–5\% in the 480–530 nm range).

### 3.5 Spectral fitting

The DOAS intelligent system (DOASIS; (Kraus, 2003)) was used to retrieve gas-phase concentrations. Optical extinction data collected in laboratory experiments were fitted using the literature absorption spectra (Sect. 3.3) and a third-degree polynomial to represent broad-band processes (e.g., temperature fluctuation, Mie scattering and extinction by aerosols). The "spectral shifting" setting in DOASIS was set to \(\pm 0.2\) nm, and stretching was disallowed.
The same parameters were used to fit the data from the ORCA field campaign except that in an effort to minimize the fit residuals, the convoluted absorption cross-section of H₂O based on the high-resolution data by (Coheur et al., 2002) was also included in the fit. The contributions of water vapor to the optical extinction was small since the relative humidity of the air sampled during the background measurement was the same as during the measurement of NO₂ or I₂. Further, the optical extinction (α) values, as per Eq. (1), were smoothed using a fourth order polynomial filter (Savitzky and Golay, 1964). Smoothing improved the root mean square (RMS) of the residuals and the fit uncertainty by a factor of ~2 (Figure S3).

3.6 Description of CRDS instrument

The IBBCEAS instrument quantified NO₂ in parallel to a blue diode laser CRDS instrument, which has been described previously (Paul and Osthoff, 2010; Odame-Ankrah, 2015). Briefly, mixing ratios of NO₂ are quantified by optical absorption using a continuous wave (cw) laser whose emission is centered at 405 nm (Power Technology IQuu2A105, Little Rock, AR, USA). The radiation is square-wave (on/off) modulated at a repetition rate of 1 kHz (50% duty cycle) and enters a 111 cm long stable resonator formed by two highly reflective mirrors (2.54 cm diameter; Advanced Thin Films, Boulder, CO, USA) in a concentric configuration. The cavity output is coupled into a 200 µm diameter, 0.22 numerical aperture, multimode optical fibre (Thorlabs M25L01) illuminating a photomultiplier tube (Hamamatsu Photonics H9433-03MOD, Japan). The ring-down decay traces are co-added and fitted to an exponential using the discrete sums algorithm described by Everest and Atkinson (2008).

The CRDS NO₂ channel was operated in parallel to a CRDS NOₓ channel, to which a small flow of O₃ in O₂ was added to convert NO to NO₂, similar to the method described by Fuchs et al. (2009). Following the O₃ addition point, the sampled air passed through a coiled reaction chamber with a total residence time of ~7 s to ensure complete titration and a linear response up to ~100 ppbv of NO (Odame-Ankrah, 2015). An identical chamber was added to the NO₂ channel to match the response times of the two channels. Mixing ratios of NO₂ and NOₓ measured by CRDS were accurate within ±10% (Osthoff et al., 2017).

3.7 Generation and delivery of gases

Figure 2b shows the setup for delivery and sampling of NO₂. NO₂ was generated by mixing the output of a standard NO cylinder (100.2±1.0 ppmv in N₂; Scott-Marrin, Riverside, CA, USA) delivered using a 20 sccm all metal MFC (MKS Instruments 1479A) with O₃ produced by illuminating a flow of O₂ (Praxair) with a 254 nm Hg pen-ray lamp (Jelight, Irvine, CA, USA) and dilution with zero air.

Iodine was purchased in a solid crystalline form (≥99.8%, Sigma-Aldrich, Oakville, ON, Canada). Small amounts were placed in a Teflon™ permeation tube (VICI Metronics, Poulbo, WA, USA); these tubes were sealed on both ends with PTFE plugs compressed with stainless steel rings and were (individually) placed in a temperature-controlled permeation chamber (Vici Metronics, model 120-1) operated with a constant air flow of ~0.3 litres per minute. The flow from the permeation chamber was diluted with zero air, yielding iodine concentrations in the range of ~70 pptv up to 21 ppbv depending on chamber temperature and permeation tube dimensions (i.e., wall thickness and length).
Ar, CO₂, CH₄, N₂, O₂, air and He were delivered from compressed gas cylinders (Praxair) in the same manner as described in section 3.2.

### 3.8 ORCA field campaign

The IBBCEAS instrument was operated alongside the CRDS during a four week long field intensive conducted at the Amphitrite Point Observatory (APO) on the west coast of Vancouver Island, British Columbia, Canada (Tokarek et al., 2017). The APO was established as a marine background monitoring site but is sporadically impacted by NOₓ emissions mainly from ship and boat traffic in the region (McKendry et al., 2014).

The IBBCEAS and CRDS instruments sampled, in parallel, from a 5.5 m long common 0.63 cm o.d. and 0.48 cm i.d. FEP Teflon™ inlet line, flooded with calibration gases and zero air at regular intervals. Zero air was generated using a custom-built zero air generation system (Odame-Ankrah, 2015), which delivered air at ambient relative humidity that was free of trace gases such as NO₂, NO, I₂, or O₃. This approach minimized absorption by H₂O from the extinction spectra which can create artifacts (Bahrini et al., 2018). A flow restriction was placed upstream of the inlet filter. When the IBBCEAS instrument was operated at a flow rate of 5 slpm, an average (±1σ) sample cell pressure of 473 (±23) hPa and inlet residence time of 2.3 s were achieved. The cell pressure varied over short time periods with a standard deviation of ±2.4 hPa. A PAN-GC (Tokarek et al., 2014), commercial NO/NOₓ and O₃ instruments (Thermo 42i and 49i), as well as a 662 nm diode laser N₂O₅ channel (Osthoff et al., 2017) also sampled off this common inlet line, resulting in all instruments periodically sampling a variety of calibration gases.

The IBBCEAS transmission spectrum was integrated for 9 s, resulting in ~90% saturation of the CCD at 500 nm. Dark spectra (to characterize the spectrometer offset) were acquired daily with the same integration time (9 s). Wavelength calibration spectra of the Hg(Ne) lamp were collected daily over a period of 2 min and showed that the spectrometer wavelength scale remained relatively unchanged (±0.02 nm) over the region of interest. The mirror reflectivity was measured prior to and after the campaign and agreed within ±(1×10⁻⁷). Data were averaged over 60 s post-campaign prior to analysis.

### 4 Results

#### 4.1 Measurements of cross-sections of pure gases

The extinction cross-sections of N₂, CO₂ (based on mirror reflectivity determined from the Ar/He ratio of scattering coefficients), O₂, air, Ar, and CH₄ (based on mirror reflectivity determined from the N₂/He ratio of scattering coefficients) in the 480–535 nm wavelength range are shown in Figure 4; values at selected wavelengths are summarized in Table 1. For N₂, Ar, and CO₂, the extinction is due to scattering only. In contrast, the spectra of O₂, air and CH₄ include optical losses due to absorption in addition to scattering. The systematic uncertainty of these data was ±2.5%; the systematic errors arise mainly from uncertainties in the mirror reflectivity (±2.3%, see Sect. 3.2) and errors in the scattering cross-section terms in Eq. (3). The precision of the data (calculated after subtracting a 4th order
polynomial from the observed cross-sections) varies from ±2.5% for the CO₂ data shown in Figure 4e to ±0.9% for the N₂ data shown in Figure 4b.

4.1.1 Nitrogen

Figure 4b shows the measured scattering cross-sections of N₂ at a temperature of 299.0±0.1 K and pressure of 879.7±0.7 hPa between 480 and 535 nm. Superimposed are n-based cross-sections predicted using Eq. (5), data by (Peck and Khanna, 1966), and the King correction factor by (Bates, 1984). In addition, the single wavelength CRDS measurement at 532.2 nm by (Sneep and Ubachs, 2005) and the nephelometer data of (Shardanand and Rao, 1977) are shown.

The IBBCEAS data are marginally larger than the n-based prediction, with the percent difference ranging from +0.2% at 525.07 nm to +1.3% at 485.03 nm (Table 1). These differences are well within the margin of measurement error (±2.5%), set in this case by the accuracy of the scattering cross-sections of He (±2%) and Ar (<1%). The IBBCEAS data differ from the CRDS data of (Sneep and Ubachs, 2005) at 532.2 nm by +7.1%, though the error bars overlap; the measurement uncertainty of the CRDS data alone is ±9.4%. The IBBCEAS measurements also differ by +4.6% at 488.0 nm and by +8.8% at 514.5 nm) from the data of (Shardanand and Rao, 1977) but are within combined measurement error (±2.5% and ±11%, respectively).

4.1.2 Argon

The scattering cross-sections of Ar at 299.0±0.1 K and 879.7±0.7 hPa are shown in Figure 4b. Superimposed are the n-based cross-sections calculated using data from (Peck and Fisher, 1964) and the King correction factor from (Bates, 1984). The single-wavelength measurement of (Sneep and Ubachs, 2005) and the nephelometer data of (Shardanand and Rao, 1977) are shown for comparison.

The observed scattering cross-sections are marginally larger than the n-based prediction, by +1.3% at shorter wavelengths and +0.21% at 515.06 nm (Table 1). These differences are within measurement error of the IBBCEAS instrument (±2.5%) inferred from the accuracy in the determination of the scattering cross-sections of He (±2%) and N₂ (±1%) used in the determination of the mirror reflectivity. The IBBCEAS cross-sections differ from the CRDS data by (Sneep and Ubachs, 2005) at 532.2 nm and are well within either measurement error bar (Figure 4b). In contrast, the CEAS values differ from the nephelometer data by -10.8% at 488.0 nm and by -5.1% at 514.5 nm, though they are within the ±11% uncertainty of the nephelometer.

4.1.3 Oxygen

The extinction cross-sections of O₂ (at a temperature of 299 K and a pressure of 880 hPa) are shown in Figure 4c next to the n-based predictions based on (Bates, 1984) and the nephelometer measurements of (Shardanand and Rao, 1977). The IBBCEAS data show two absorption bands due to the oxygen dimer, O₄, centered at 477 nm and 532 nm (Thalman and Volkamer, 2013). In the 490 – 515 nm wavelength interval, the contribution of these absorption bands to the total
extinction is negligible (<0.2% at 515 nm), i.e., the extinction is dominated by scattering. In this region, the observed cross-sections are slightly larger than the \( n \)-based data of (Bates, 1984): the differences range from +8.3% at 495.08 nm to +2.5% at 515.06 nm (Table 1). Relative to the nephelometer measurements, the IBBCEAS data differ by +8.7% at 488 nm and by +15.3% at 514.5 nm.

We calculated the absorption cross-section of \( \text{O}_4 \) by subtracting the scattering cross-section of (Bates, 1984), upshifted by \(+3.86\times10^{-28} \text{ cm}^2 \text{ molecule}^{-1}\) (i.e., by 6%) to match the \( n \)-based data to the observed extinction from 487 nm to 516 nm, from the extinction shown in Figure 4c, and dividing by the number density of \( \text{O}_2 \) (2.13×10^{19} \text{ molecules cm}^{-3}).

The result is shown in Figure S4. The error for this absorption cross-section calculation is estimated at ±8.5%, with the largest source of error being the correction to the scattering cross-section extrapolated from the region where absorption is negligible. For the smaller band between 520 and 540 nm, the observed cross-section of \((1.08\pm0.09)\times10^{-46} \text{ cm}^5 \text{ molecule}^{-2}\) is in agreement with recent room-temperature measurements by other groups (Table S1). For the larger band between 467 and 485 nm, the peak cross-section of \((6.2\pm0.5)\times10^{-46} \text{ cm}^5 \text{ molecule}^{-2}\) is smaller than that reported in recent measurements (Thalman and Volkamer, 2013; Sneep et al., 2006), though the shape of the peak is identical and the error bars overlap.

### 4.1.4 Air

Figure 4d shows the extinction spectrum of ultrapure air ("zero" grade, Praxair) at a temperature of (298.5±0.1) K and pressure of 879.7±0.7 hPa. Superimposed is the \( n \)-based prediction from the refractive index data of (Penndorf, 1957) and King correction factor from (Bodhaine et al., 1999).

The sample cylinder contains a sufficiently high quantity of \( \text{O}_2 \) (~19.5% by volume, Praxair) for \( \text{O}_4 \) absorption bands to appear at 477.5 and 531.5 nm. In the 495 - 515 nm wavelength region, the cross-sections observed by IBBCEAS are slightly larger than the \( n \)-based prediction, by +4.0%, +3.0%, and +6.8% at 495, 505, and 515 nm, respectively (Table 1).

### 4.1.5 Carbon dioxide

Figure 4e shows the scattering cross-sections of \( \text{CO}_2 \) at (299.0±0.1) K and (879.7±0.7 hPa for the 475 – 540 nm wavelength interval. Superimposed are the \( n \)-based prediction based on (Bideau-Mehu et al., 1973), nephelometer measurements (Shardanan and Rao, 1977), and a CRDS measurement at 532.2 nm (Sneep and Ubachs, 2005). The observed scattering cross-sections differ from the \( n \)-based prediction by -2.9%, +2.4% and -2.8% at 485 nm, 505 nm, and 525 nm, respectively (Table 1). In contrast, the CRDS measurement at 532.2 nm, which has a relatively high uncertainty of ±6.5% at the 1σ level, is 11% lower than the IBBCEAS measurement. The nephelometer measurements (Shardanan and Rao, 1977), on the other hand, are significantly larger than the other data shown and appear to be in error.

### 4.1.6 Methane
Figure 4f shows the extinction spectrum of CH$_4$ (research grade, 99.97%) for the 475 – 550 nm interval at (298.5±0.1) K and 879.7±0.7 hPa. The CH$_4$ spectrum in this region contains a number of combination and overtone absorption bands near 484.7, 486.1, 509.6, 522.0, and 543.4 nm that have been assigned by (Giver, 1978). These bands are relevant to studies simulating the atmospheres of Jovian planets (e.g., Uranus, Neptune) and Saturn’s moon Titan that contain CH$_4$ (Karkoschka, 1994). Superimposed are CRDS data by (Sneep and Ubachs, 2005) and the $n$-based scattering cross-sections, calculated using the parameterization by Sneep and Ubachs, and refractive index data from (Hohm, 1993), assuming a depolarization ratio of unity and nephelometer data by (Shardanand and Rao, 1977) extrapolated using Eq. (5) (dashed line). In spite of the many absorption bands, there are small windows where the optical extinction appears to be dominated by scattering and a comparison with literature is feasible. There is very little difference (within combined measurement errors) between IBBCEAS and interpolated nephelometer data at those wavelengths. At 492.06 nm and 527.28 nm, for example, the data are within -0.07% and 0.17%, respectively (Table 1). There is also reasonable agreement between the IBBCEAS and CRDS data 532.2 nm, which differ by 4.7% but compares well with the total IBBCEAS uncertainty of 4.6% for CH$_4$.

4.2 Measurement of trace gas mixing ratios

4.2.1 Nitrogen dioxide

An example of a spectral retrieval for NO$_2$ in ambient air is shown on Figure 5a. The figure shows the measured optical extinction ($\alpha$) for a routine calibration period during the ORCA campaign on 22 Jul 2015 at 11:52:07 to 11:57:02 (UTC). Superimposed is a fit determined with DOASIS. An NO$_2$ mixing ratio of (11.6 ± 0.4) ppbv was retrieved, corresponding to an ambient air mixing ratio of (13.9 ± 1.0) ppbv when RL is factored in. The residual spectrum is lacking structure, indicating that other absorbers are not significant in this wavelength region. During the ORCA campaign, the inlet of the IBBCEAS instrument (and of the CRDS instrument, which sampled in parallel) was overflowed every 30 min with a standard gas mixture of ~20 ppbv NOx containing up to 16 ppbv of NO$_2$ in zero air and with ~130 ppbv of NO added to ambient air. The zero air was generated using a scrubber constructed in-house that delivered air with a similar moisture content as ambient air. A subset of these data (and the ambient air data sampled in between) is shown in Figure 6a.

High concentrations of NO in air are prone to oxidation (by O$_3$ and, to a lesser degree, by O$_2$) to NO$_2$ (Atkinson et al., 2004). Because the CRDS had a longer inlet residence time (7 s) than the IBBCEAS instrument (2.3 s), it observed greater conversion of NO to NO$_2$ when the high NO concentration standard was sampled in an ambient air matrix. On the other hand, when the lower concentration NOx standard was sampled in O$_3$-free air, the two instruments were in better agreement (Figure 6a).

Shown in Figure 7a is a scatter plot of all of the NOx calibration data. This plot shows a linear relationship with a slope of 1.11±0.01, an intercept of 0.2±0.1 ppbv, and $r^2 = 0.975$. The slope of the line in Figure 7a reveals an 11% systematic difference in the measurement of the calibration standard.

The median NO$_2$ mixing ratio during ORCA was 1.24 ppbv. Shown in Figure 6b is a time series of a subset of ambient air NO$_2$ measurements. The IBBCEAS NO$_2$ data clearly exhibit more scatter than the CRDS NO$_2$ data and occasionally
fall below zero. For ambient air data collected on 18-19 Jul 2015, the scatter plot of IBBCEAS and CRDS NO\(_2\) data (Figure 7b) has the same slope (1.12±0.02) as that shown in Figure 7a, while the scatter plot of the entire campaign has a slope of 1.02±0.01 (Figure 7C). When data are filtered by removing all IBBCEAS points below a factor of three times the standard deviation of a blank measurement for 60 s (~1 ppbv; see Sect. 4.3), the slope of the scatter plot, when forced through an intercept of zero, is 1.18±0.01 (r\(^2\) = 0.70), suggesting that the IBBCEAS are biased high.

### 4.2.2 Iodine species (I\(_2\), OIO)

Figure 5b shows an example retrieval for I\(_2\). The extinction spectrum was recorded during the ORCA campaign on 18 Jul 2015, when I\(_2\) from a permeation source had been added to the inlet and represents a 60 s average. A mixing ratio of (10.1±0.2) ppbv was retrieved in this example.

Figure S5 shows spectra of laboratory generated I\(_2\) samples and their respective absorption spectra, fits, and residuals. Fit results near 20 pptv showed large residuals (±27%) indicating that the IBBCEAS instrument was near its detection limit.

A sample time series of laboratory I\(_2\) measurements (30 s averaged data) is shown in Figure S6. Gas streams containing I\(_2\) were generated using four permeation tubes of different wall thickness, that were exchanged while the output of the permeation was bypassed and the IBBCEAS sampled zero air. The IBBCEAS instrument responded rapidly to concentration changes: for example, at 22:05, the response 30 s after "zeroing" was 10% of the preceding value, indicating that memory effects (from slow adsorption / desorption kinetics of iodine on the inner walls of the inlet) were negligible.

Figure S7 shows a sample time series of I\(_2\) mixing ratios during the ORCA campaign. Concentrations of I\(_2\) (and of OIO, not shown) in ambient air were below the instrument's detection limits. At 22:30 UTC, I\(_2\) from a diffusion source was added to the inlet. While the transmission of iodine through inlets was not systematically investigated in this work, the square-wave response and quick rise and fall times suggest the absence of inlet transmission losses.

### 4.3 Accuracy and limits of detection

The accuracy of the IBBCEAS NO\(_2\) measurement is influenced by uncertainties in the absorption cross-section of NO\(_2\) (±3%) (Voigt et al., 2002), fit errors ±(3 – 5%), which can be reduced to ±(2 – 4)% by smoothing, scattering cross-sections, i.e., mirror reflectivity (±2.5%; Sect. 3.2 and 4.1), R\(_L\) (±5%; Sect. 3.3), and errors in the mass flow controller reading (±1%), sample cell pressure readout (±0.5%), and temperature measurement (±0.7%). The total uncertainty, expressed as the square root of the individual errors summed in quadrature, is ±(7 – 8)%. Not included in this estimate are errors arising from interpolation of infrequent mirror reflectivity and R\(_L\) determinations in the field. The limits of detection (LOD) were assessed through Allan deviation analyses (Werle et al., 1993). For NO\(_2\) sampled at a flow of 1.5 slpm and cell pressure of 890 hPa, the Allan deviation was ±360 pptv for 10 s data, ±135 pptv for 60
predicted NO₂ data, and ±63 pptv for 5 min data averages (Figure 8a). At the higher sample flow of 5 slpm and reduced cell pressure of 466 hPa used during the ORCA campaign, the Allan deviation was ±164 pptv for 334 s data (Figure S8).

For I₂ in laboratory-generated samples, typical 1σ fit errors for 60 s averaged data were ±7 pptv when 21 pptv I₂ were sampled and ±9 pptv when 544 pptv I₂ were sampled (Figure S6). The accuracy of I₂ data is, in principle, of similar magnitude to that of the NO₂ data, except that it also depends on knowledge of inlet transmission efficiency, which was not assessed in this work. The Allan deviation plot in Figure 8b demonstrates 1σ measurement precisions for I₂ of ±49 pptv for 60 s and ±22 pptv for 5 min averaged data. During ORCA, the 1σ precisions were ±120 pptv for 60 s and ±60 pptv for 5 min data, respectively.

For OIO, the Allan deviation analysis gives 1σ measurement precisions of ±5.7 pptv for 60 s and ±2.3 pptv for 5 min averaged data (Figure S9b) in the laboratory.

5 Discussion

The IBBCEAS instrument described in this work adds to a growing number of instruments designed for measurement of atmospheric trace gases (Table 2). It differentiates itself foremost through its wavelength region, where several trace gases of atmospheric interest (e.g., NO₂, I₂, IO, and OIO) absorb (Figure 1). Measurements of optical absorption in the cyan region enable simultaneous quantification of I₂, and, potentially, IO, and OIO in a single channel. Currently, such measurements require multiple detection channels, for example quantification of I₂ and OIO mixing ratios using the 525 – 555 nm range and those of IO the 420 – 460 nm window in a separate channel (Vaughan et al., 2008). A reduction of channels and LEDs corresponds to savings in space and power requirements, important considerations in the field.

As such, this paper has laid some of the ground work for future measurements in the cyan spectral region, in that we measured relevant scattering and absorption cross-sections of pure gases (see S.I.). Such information is needed to determine mirror reflectivity and is useful to probe the consistency of scattering cross-sections reported for this wavelength region (of which there have been relatively few) and, hopefully, improve upon their accuracy, to better describe transmission of radiation through the atmosphere.

Scattering cross-section measurements for non-absorbing gases agree with recent literature values (Figure 4 and Table 1). For example, the IBBCEAS scattering cross-section measurements agree, within the combined experimental uncertainties (1σ), with the CRDS data by (Sneep and Ubachs, 2005) at 532.2 nm for N₂, Ar, CO₂, and CH₄, and with the nephelometer measurements of (Shardanand and Rao, 1977) at 488.0 and 514.5 nm for N₂, Ar, O₂, and CH₄. For CO₂, the IBBCEAS data closely match the data by (Bideau-Mehu et al., 1973) and recent data by (He et al., 2018); the older data by (Shardanand and Rao, 1977), in contrast, appear high (Figure 4e).

In the case of CH₄, to lesser extent, O₂ and, air, the analysis is complicated by absorption lines. For O₂, our data and derived collisional-induced absorption cross-sections agree with literature (Table S1). For regions that appear to be free of absorption bands, the IBBCEAS data for CH₄ (Figure 4f) agree with cross-section measurements of (Shardanand and Rao, 1977) but not with the more recent work of (Hohm, 1993) whose data appear high. The CRDS data point by (Sneep and Ubachs, 2005) is on a shoulder of a large absorption band and hence not a valid measurement of scattering but extinction cross-section; their data agrees with the extinction cross-section observed in this work.
Accurate knowledge of the scattering cross-section of CH₄ is important to the study of planetary bodies with atmospheric content of CH₄ such as Saturn's moon Titan. Future studies should re-examine the scattering cross-section measurements of CH₄ to resolve the reported differences.

The detection limit for NO₂ achieved under laboratory conditions in this work (63 pptv for 5 min data) is of similar magnitude as those by instruments operated in other wavelength regions (Table 2). However, the IBBCEAS measurement precision in this work was surpassed by the more mature blue diode CRDS, though future upgrades (see below) may improve the IBBCEAS precision. On the other hand, the IBBCEAS may ultimately be more accurate. Unlike IBBCEAS where all absorbing molecules are incorporated in the fit, the measurement of NO₂ by blue diode laser CRDS is prone to potential interference from molecules that absorb at 405 nm such as glyoxal and methyl glyoxal (Fuchs et al., 2009). For example, Fuchs et al. estimated that the presence of glyoxal could introduce an interference of ~1% in polluted and up to 10% in forested environments (Fuchs et al., 2009). The low precision of the data in the scatter plot shown in Figure 7c prevents us from drawing a definitive conclusion as to the magnitude of such interferences. Still, future comparisons of IBBCEAS and blue diode CRDS measurements of ambient NO₂ should be conducted. The data presented in this manuscript show that accurate measurements of NO₂ in ambient air by a cyan IBBCEAS are possible.

An important parameter in any IBBCEAS measurement is the effective cavity length. Duan et al. recently summarized past practices in its determination and found that these practices vary considerably between groups (Duan et al., 2018). In this work, the necessary correction (R_L = 1.28 at 2.0 slpm sample flow rate) differed substantially from the physical dimension of the cell (1.39), underlining its importance for accurate measurements. However, it is unclear to what extent R_L varies between molecules which will need to be investigated. To improve the accuracy of future measurements, we will deploy more frequent zeroing and verify R_L periodically, for example by periodic sampling of molecular oxygen and measuring O₄ concentration.

The sensitivity for I₂ and OIO (22 and 2.3 pptv for 5 min averaged data under laboratory conditions) suffices for their quantification in environmental chamber studies (Dixneuf et al., 2009). Further, these LODs are below maximum I₂ and OIO abundances reported at Mace Head, Ireland, of 94 and 13 pptv (Bitter et al., 2005) and 61 and 9.2 pptv (Peters et al., 2005), respectively, but above the maximum I₂ level of 4 pptv reported in California (Finley and Saltzman, 2008). This implies that iodine species on the West coast of British Columbia, Canada, might have been detected if the instrument had been operated optimally. Even then, the LOD for I₂ of ~100 pptv (2σ, 60 s average) is larger than the LOD of 26 pptv (2σ, 60 s average) reported by Vaughan et al. (2008). This suggests that improvements are possible. One area for improvement is the thermal management of the LED. Its intensity and wavelength drifts with temperature, necessitating temperature stabilization to achieve a constant emission profile. In this work, the cyan LED was stabilized by mounting a single Peltier thermoelectric module and thermocouple between the heat sink and the LED. When evaluated in the climate-controlled laboratory, this yielded a cavity emission profile that varied along the entire wavelength range (446.9–563.2 nm) of the spectrometer by ±15 counts (Figure S10). At 500 nm, this corresponded to an absorption coefficient of ±1×10⁻⁹ cm⁻¹. During the field deployment, however, the LED was subject to greater output fluctuations, since the trailer temperature was not as well controlled as in the laboratory, and thermal gradients between the LED and thermocouple may have come into play.
When deployed in the field, the performance of the IBBCEAS instrument was also compromised by variable cell pressure which added noise to the optical extinction, caused in part by the large pressure drop from ~1013 to ~467 hPa. Furthermore, we discovered post-campaign that the alignment of the round-to-linear fiber bundle is very sensitive to vibrations, which would have added additional noise during the field campaign. In future deployments, improved pressure, temperature and vibrational stabilization of the sample cell (as it is common in aircraft deployments, for example) and instrument will be paramount.

\(^a\) The absolute uncertainty is ±2.5% (see Sect. 4.1); \(^b,c\) See text for references of \( n \)-based scattering cross-sections and references therein for corresponding calculations of King (King, 1923) correction factors; \(^d\) From (Sneepr and Ubachs,
2005); uncertainty is stated as 1σ. The ratio of N₂/O₂ in the cylinder was ~ 80.5/19.5; Comparison is to the fitted expression to the data set of (Sharanand and Rao, 1977).
