27 **Abstract**

28 Satellite retrieval of vertical column densities (VCDs) of tropospheric nitrogen dioxide
29 (NO_2) is critical for NO_x pollution and impact evaluation. For regions with high aerosol
30 loadings, the retrieval accuracy is greatly affected by whether aerosol optical effects are
31 treated implicitly (as additional “effective” clouds) or explicitly, among other factors.
32 Our previous POMINO algorithm explicitly accounts for aerosol effects to improve the
33 retrieval especially in polluted situations over China, by using aerosol information from
34 GEOS-Chem simulations with further monthly constraints by MODIS/Aqua aerosol
35 optical depth (AOD) data. Here we present a major algorithm update, POMINO v1.1,
36 by constructing a monthly climatological data set of aerosol extinction profiles, based
37 on Level-2 CALIOP/CALIPSO data over 2007–2015, to better constrain the modeled
38 aerosol vertical profiles.

39 We find that GEOS-Chem captures the month-to-month variation of CALIOP aerosol
40 layer height but with a systematic underestimate by about 300–600 m (season and
41 location dependent), due to a too strong negative vertical gradient of extinction above
42 1 km. Correcting the model aerosol extinction profiles results in small changes in
43 retrieved cloud fraction, increases in cloud top pressure (within 2–6% in most cases),
44 and increases in tropospheric NO_2 VCD by 4–16% over China on a monthly basis in
45 2012. The improved NO_2 VCDs (in POMINO v1.1) are more consistent with
46 independent ground-based MAX-DOAS observations ($R^2 = 0.80$, NMB = -3.4%, for
47 162 pixels in 49 days) than POMINO ($R^2 = 0.80$, NMB = -9.6%), DOMINO v2 ($R^2 =$

48 0.68, NMB = -2.1%), and QA4ECV ($R^2 = 0.75$, NMB = -22.0%) are. Especially on
49 haze days, R^2 reaches 0.76 for POMINO v1.1, much higher than that for POMINO
50 (0.68), DOMINO v2 (0.38), and QA4ECV (0.34). Furthermore, the increase in cloud
51 pressure likely reveals a more realistic vertical relationship between cloud and aerosol
52 layers, with aerosols situated above the clouds in certain months instead of always
53 below the clouds. The POMINO v1.1 algorithm is a core step towards our next public
54 release of data product (POMINO v2), and it will also be applied to the recently
55 launched S5P-TropOMI sensor.

56 **1. Introduction**

57 Air pollution is a major environmental problem in China. In particular, China has
58 become the world's largest emitting country of nitrogen oxides ($\text{NO}_x = \text{NO} + \text{NO}_2$) due
59 to its rapid economic growth, heavy industries, coal-dominated energy sources, and
60 relatively weak emission control (Cui et al., 2016; Lin et al., 2014a; Stavrou et al.,
61 2016; Zhang et al., 2009). Tropospheric vertical column densities (VCDs) of nitrogen
62 dioxide (NO_2) retrieved from the Ozone Monitoring Instrument (OMI) onboard the
63 Earth Observing System (EOS) Aura satellite have been widely used to monitor and
64 analyze NO_x pollution over China because of its high spatiotemporal coverage (e.g.
65 (Lin et al., 2010; Miyazaki and Eskes, 2013; Verstraeten et al., 2015; Zhao and Wang,
66 2009). However, NO_2 retrieved from OMI and other space-borne instruments are
67 subject to errors in the conversion process from radiance to VCD, particularly with
68 respect to the calculation of tropospheric air mass factor (AMF) that is used to convert
69 tropospheric slant column density to VCD (e.g. Boersma et al., 2011; Bucsela et al.,
70 2013; Lin et al., 2015; Lorente et al., 2017).

71 Most current-generation NO_2 algorithms do not explicitly account for the effects of
72 aerosols on NO_2 AMFs and on prerequisite cloud parameter retrievals. These retrievals
73 often adopt an implicit approach wherein cloud algorithms retrieve "effective cloud"

74 parameters that include the optical effects of aerosols. This implicit method is based on
75 aerosols exerting an effect on the top-of-atmosphere radiance level, whereas the
76 assumed cloud model does not account for the presence of aerosols in the atmosphere
77 (Stammes et al., 2008; Veefkind et al., 2016; Wang et al., 2008b; Wang and Stammes,
78 2014). In the absence of clouds, an aerosol optical thickness of 1 is then interpreted as
79 an effective cloud fraction of ± 0.10 , and the value also depends on the aerosol
80 properties (scattering or absorbing), true surface albedo and geometry angles (Chimot
81 et al., 2016) with an effective cloud pressure closely related to the aerosol layer, at least
82 for aerosols of predominantly scattering nature (e.g. Boersma et al., 2004, 2011,
83 Castellanos et al., 2014, 2015). However, in polluted situations with high aerosol
84 loadings and more absorbing aerosol types, which often occur over China and many
85 other developing regions, the implicit method can result in considerable biases
86 (Castellanos et al., 2014, 2015; Chimot et al., 2016; Kanaya et al., 2014; Lin et al.,
87 2014b).

88 Lin et al. (2014b, 2015) established the POMINO NO₂ algorithm, which builds on the
89 DOMINO v2 algorithm (for OMI NO₂ slant columns and stratospheric correction), but
90 improves upon it through a more sophisticated AMF calculation over China. In
91 POMINO, the effects of aerosols on cloud retrievals and NO₂ AMFs are explicitly
92 accounted for. In particular, daily information on aerosol optical properties such as
93 aerosol optical depth (AOD), single scattering albedo (SSA), phase function and
94 vertical extinction profiles are taken from nested Asian GEOS-Chem v9-02 simulations.
95 The modeled AOD at 550 nm is further constrained by MODIS/Aqua monthly AOD,
96 with the correction applied to other wavelengths based on modeled aerosol refractive
97 indices (Lin et al., 2014b). However, the POMINO algorithm does not include an
98 observation-based constraint on the vertical profile of aerosols, whose altitude relative
99 to NO₂ has strong and complex influences on NO₂ retrieval (Castellanos et al., 2015;
100 Leitão et al., 2010; Lin et al., 2014b). This study improves upon the POMINO algorithm

101 by incorporating CALIOP monthly climatology of aerosol vertical extinction profiles
102 to correct for model biases.

103 The CALIOP lidar, carried on the sun-synchronous CALIPSO satellite, has been
104 acquiring global aerosol extinction profiles since June 2006 (Winker et al., 2010).
105 CALIPSO and Aura are both parts of the National Aeronautics and Space
106 Administration (NASA) A-train constellation of satellites. The overpass time of
107 CALIOP/CALIPSO is only 15 minutes later than OMI/Aura. In spite of issues with the
108 detection limit, radar ratio selection and cloud contamination that cause some biases in
109 CALIOP aerosol extinction vertical profiles (Amiridis et al., 2015; Koffi et al., 2012;
110 Winker et al., 2013), comparisons of aerosol extinction profiles between ground-based
111 lidar and CALIOP show good agreements (Kacenelenbogen et al., 2014; Kim et al.,
112 2009; Misra et al., 2012). However, CALIOP is a nadir-viewing instrument that
113 measures the atmosphere along the satellite ground-track with a narrow field-of-view.
114 This means that the daily geographical coverage of CALIOP is much smaller than that
115 of OMI. Thus previous studies often used monthly/seasonal regional mean CALIOP
116 data to study aerosol vertical distributions or to evaluate model simulations (Chazette
117 et al., 2010; Johnson et al., 2012; Koffi et al., 2012; Ma and Yu, 2014; Sareen et al.,
118 2010).

119 There exist a few CALIOP Level-3 gridded datasets, such as LIVAS (Amiridis et al.
120 2015) and NASA official Level-3 monthly dataset (Winker et al., 2013). However,
121 LIVAS is an annual average day-night combined product, not suitable to be applied to
122 OMI NO₂ retrievals (around early afternoon, and in need of a higher temporal resolution
123 than annual). The horizontal resolution (2° long. × 5° lat.) of NASA official product
124 is much coarser than OMI footprints and the GEOS-Chem model resolution.

125 Here we construct a custom monthly climatology of aerosol vertical extinction profiles
126 based on 9-years (2007–2015) worth of CALIOP Version 3 Level-2 532 nm data. On a

127 climatological basis, we use the CALIOP monthly data to adjust GEOS-Chem profiles
128 in each grid cell for each day of the same month in any year. We then use the corrected
129 GEOS-Chem vertical extinction profiles in the retrievals of cloud parameters and NO₂.
130 Finally, we evaluate our updated POMINO retrieval (hereafter referred to as POMINO
131 v1.1), our previous POMINO product, DOMINO v2, and the newly released Quality
132 Assurance for Essential Climate Variables product (QA4ECV, see Appendix A), using
133 ground-based MAX-DOAS NO₂ column measurements at three urban/suburban sites
134 in East China for the year of 2012 and several months in 2008/2009.

135 Section 2 describes the construction of CALIOP aerosol extinction vertical profile
136 monthly climatology, the POMINO v1.1 retrieval approach, and the MAX-DOAS data.
137 It also presents the criteria for comparing different NO₂ retrieval products and for
138 selecting coincident OMI and MAX-DOAS data. Section 3 compares our CALIOP
139 climatology with NASA's official Level-3 CALIOP dataset and GEOS-Chem
140 simulation results. Sections 4 and 5 compare POMINO v1.1 to POMINO to analyze the
141 influence of improved aerosol vertical profiles on retrievals of cloud parameters and
142 NO₂ VCDs, respectively. Section 6 evaluates POMINO, POMINO v1.1, DOMNO v2,
143 and QA4ECV NO₂ VCD products using the MAX-DOAS data. Section 7 concludes
144 our study.

145 **2. Data and methods**

146 2.1 CALIOP monthly mean extinction profile climatology

147 CALIOP is a dual-wavelength polarization lidar measuring attenuated backscatter
148 radiation at 532 and 1064 nm since June 2006. The vertical resolution of aerosol
149 extinction profiles is 30 m below 8.2 km and 60 m up to 20.2 km (Winker et al., 2013),
150 with a total of 399 sampled altitudes. The horizontal resolution of CALIOP scenes is

151 335 m along the orbital track and is given over a 5 km horizontal resolution in Level-2
152 data.

153 As detailed in Appendix B, we use the daily all-sky Version 3 CALIOP Level-2 aerosol
154 profile product at 532 nm from 2007 to 2015 to construct a monthly Level-3
155 climatological dataset of aerosol extinction profiles over China and nearby regions.
156 This dataset is constructed on the GEOS-Chem model grid (0.667° long. \times 0.5° lat.)
157 and vertical resolution (47 layers, with 36 layers or so in the troposphere). The ratio of
158 climatological monthly CALIOP to monthly GEOS-Chem profiles represents the
159 scaling profile to adjust the daily GEOS-Chem profiles in the same month (see Sect.
160 2.2)

161 *2.2 POMINO v1.1 retrieval approach*

162 The NO₂ retrieval consists of three steps. First, the total NO₂ slant columns density
163 (SCD) is retrieved using the Differential Optical Absorption Spectroscopy (DOAS)
164 technique (for the 405-465 nm spectral window in the case of OMI). The uncertainty
165 of the SCD is determined by the appropriateness of the fitting technique, the instrument
166 noise, the choice of fitting window, and the orthogonality of the absorbers' cross
167 sections (Bucsela et al., 2006; van Geffen et al., 2015; Lerot et al., 2010; Richter et al.,
168 2011; Zara et al., 2018). The NO₂ SCD in DOMINO v2 has a bias at about $0.5\sim 1.3 \times$
169 10^{15} molec. cm^{-2} (Belmonte Rivas et al., 2014; Dirksen et al., 2011; van Geffen et al.,
170 2015; Marchenko et al., 2015; Zara et al., 2018), which can be reduced by improving
171 wavelength calibration and including O₂-O₂ and liquid water absorption in the fitting
172 model (van Geffen et al., 2015; Zara et al., 2018). The tropospheric SCD is then
173 obtained by subtracting the stratospheric SCD from the total SCD. The bias in the total
174 SCD is mostly absorbed by this stratospheric separation step, which may not propagate
175 into the tropospheric SCD (van Geffen et al., 2015). The last step converts the
176 tropospheric SCD to VCD by using the tropospheric AMF ($\text{VCD} = \text{SCD} / \text{AMF}$). The

177 tropospheric AMF is calculated at 438 nm by using look-up tables (in most retrieval
178 algorithms) or online radiative transfer modeling (in POMINO) driven by ancillary
179 parameters, which act as the dominant source of errors in retrieved NO₂ VCD data over
180 polluted areas (Boersma et al., 2007; Lin et al., 2014b, 2015; Lorente et al., 2017).

181 Our POMINO algorithm focuses on the tropospheric AMF calculation over China and
182 nearby regions, taking the tropospheric SCD (Dirksen et al., 2011) from DOMINO v2
183 (Boersma et al., 2011). POMINO improves upon the DOMINO v2 algorithm in the
184 treatment of aerosols, surface reflectance, online radiative transfer calculations, spatial
185 resolution of NO₂, temperature and pressure vertical profiles, and consistency between
186 cloud and NO₂ retrievals (Lin et al., 2014b, 2015). In brief, we use the parallelized
187 LIDORT-driven AMFv6 package to derive both cloud parameters and tropospheric
188 NO₂ AMFs for individual OMI pixels online (rather than using a look-up table). NO₂
189 vertical profiles, aerosol optical properties and aerosol vertical profiles are taken from
190 the nested GEOS-Chem model over Asia (0.667° long. \times 0.5° lat. before May 2013
191 and 0.3125° long. \times 0.25° lat. afterwards), and pressure and temperature profiles are
192 taken from the GEOS-5 and GEOS-FP assimilated meteorological fields that drive
193 GEOS-Chem simulations. Model aerosols are further adjusted by satellite data (see
194 below). We adjust the pressure profiles based on the difference in elevation between
195 the pixel center and the matching model grid cell (Zhou et al., 2010). We also account
196 for the effects of surface bidirectional reflectance distribution function (BRDF) (Lin et
197 al., 2014b; Zhou et al., 2010) by taking three kernel parameters (isotropic, volumetric
198 and geometric) from the MODIS MCD43C2 data set at 440 nm (Lucht et al., 2000).

199 As a prerequisite to the POMINO NO₂ retrieval, clouds are retrieved through the O₂-
200 O₂ algorithm (Acarreta et al., 2004; Stammes et al., 2008) with O₂-O₂ SCDs from
201 OMCLDO₂, and with pressure, temperature, surface reflectance, aerosols and other
202 ancillary information consistent with the NO₂ retrieval. Note that the treatment of cloud

203 scattering (as “effective” Lambertian reflector, as in other NO₂ algorithms) is different
204 from the treatment of aerosol scattering/absorption (vertically resolved based on the
205 Mie scheme).

206 POMINO uses the temporally and spatially varying aerosol information, including
207 AOD, single scattering albedo (SSA), phase function and vertical profiles from GEOS-
208 Chem simulations. POMINO v1.1 (this work) further uses CALIOP data to constrain
209 the shape of aerosol vertical extinction profile. We run the model at a resolution of
210 0.3125° long.× 0.25° lat. before May 2013 and 0.667° long.× 0.5° lat. afterwards, as
211 determined by the resolution of the driving meteorological fields. We then regrid the
212 finer resolution model results to 0.667° long.× 0.5° lat., to be consistent with the
213 CALIOP data grid. We then sample the model data at times and locations with valid
214 CALIOP data at 532 nm to establish the model monthly climatology.

215 For any month in a grid cell, we divide the CALIOP monthly climatology of aerosol
216 extinction profile shape by model climatological profile shape to obtain a unitless
217 scaling profile (Eq. 1), and apply this scaling profile to all days of that month in all
218 years (Eq. 2). Such a climatological adjustment is based on the assumption that
219 systematic model limitations are month-dependent and persist over the years and days
220 (e.g., a too strong vertical gradient, see Sect. 3.3). Although this monthly adjustment
221 means discontinuity on the day-to-day basis (e.g., from the last day of a month to the
222 first day of the next month), such discontinuity does not significantly affect the NO₂
223 retrieval, based on our sensitivity test.

224 In Eqs. 1 and 2, E^C represents the CALIOP climatological aerosol extinction
225 coefficient, E^G the GEOS-Chem extinction, E^{Gr} the post-scaling model extinction,
226 and R the scaling profile. The subscript i denotes a grid cell, k a vertical layer, d a day,
227 m a month, and y a year. Note that in Eq. 1, the extinction coefficient at each layer is
228 normalized relative to the maximum value of that profile. This procedure ensures that

229 the scaling is based on the relative shape of the extinction profile and is thus
 230 independent of the accuracies of CALIOP and GEOS-Chem AOD. We keep the
 231 absolute AOD value of GEOS-Chem unchanged in this step.

$$232 \quad R_{i,k,m} = \frac{E_{i,k,m}^C / \max(E_{i,k,m}^C)}{E_{i,k,m}^G / \max(E_{i,k,m}^G)} \quad (1)$$

$$233 \quad E_{i,k,d,m,y}^{Gr} = E_{i,k,d,m,y}^G \times R_{i,k,m} \quad (2)$$

234 In POMINO, the GEOS-Chem AOD are further constrained by a MODIS/Aqua
 235 Collection 5.1 monthly AOD dataset compiled on the model grid (Lin et al., 2014b,
 236 2015). POMINO v1.1 uses the Collection 5.1 AOD data before May 2013 and
 237 Collection 6 data afterwards. For adjustment, model AOD are projected to a
 238 $0.667^\circ \text{ long.} \times 0.5^\circ \text{ lat.}$ grid and then sampled at times and locations with valid MODIS
 239 data (Lin et al., 2015). As shown in Eq. 3, τ^M denotes MODIS AOD, τ^G GEOS-
 240 Chem AOD, and τ^{Mr} post-adjustment model AOD. The subscript i denotes a grid
 241 cell, d a day, m a month, and y a year. This AOD adjustment ensures that in any month,
 242 monthly mean GEOS-Chem AOD is the same as MODIS AOD while the modeled day-
 243 to-day variability is kept.

$$244 \quad \tau_{i,d,m,y}^{Gr} = \frac{\tau_{i,m,y}^M}{\tau_{i,m,y}^G} \times \tau_{i,d,m,y}^G \quad (3)$$

245 Equations 4–5 show the complex effects of aerosols in calculating the AMF for any
 246 pixel. The AMF is the linear sum of tropospheric layer contributions to the slant column
 247 weighted by the vertical sub columns (Eq. 4). The box AMF, amf_k , describes the
 248 sensitivity of NO₂ SCD to layer k , and $x_{a,k}$ represent the subcolumn of layer k from
 249 a priori NO₂ profile. The l represent the first integrated layer, which is the layer above
 250 the ground for clear sky, or the layer above cloud top for cloudy sky. The t represent
 251 the tropopause layer. POMINO assumes the independent pixel approximation (IPA)

252 (Martin et al., 2002; Boersma et al., 2002). This means that the calculated AMF for any
 253 pixel consists of a fully cloudy-sky portion (AMF_{clr}) and a fully clear-sky portion
 254 (AMF_{cld}), with weights based on the cloud radiance fraction ($CRF = \frac{CF \cdot I_{cld}}{(1-CF) \cdot I_{clr} + CF \cdot I_{cld}}$,
 255 where I_{clr} and I_{cld} are radiance from the clear-sky part and fully cloudy part of the
 256 pixel, respectively.) (Eq. 5). AMF_{cld} is affected by above-cloud aerosols, and AMF_{clr}
 257 is affected by aerosols in the entire column. Also, aerosols affect the retrieval of CRF.
 258 Thus, the improvement of aerosol vertical profile in POMINO v1.1 affects all the three
 259 quantities in Eq. 5 and thus leads to complex impacts on retrieved NO_2 VCD.

$$260 \quad AMF = \frac{\sum_l^t amf_k x_{a,k}}{\sum_l^t x_{a,k}} \quad (4)$$

$$261 \quad AMF = AMF_{cld} \cdot CRF + AMF_{clr} \cdot (1 - CRF) \quad (5)$$

262 2.3 OMI pixel selection to evaluate POMINO v1.1, POMINO, DOMINO v2, and 263 QA4ECV

264 We exclude OMI pixels affected by row anomaly (Schenkeveld et al., 2017) or with
 265 high albedo caused by icy/snowy ground. To screen out cloudy scenes, we choose
 266 pixels with CRF below 50% (effective cloud fraction is typically below 20%) in
 267 POMINO.

268 The selection of CRF threshold influences the validity of pixels. The “effective” CRF
 269 in DOMINO implicitly includes the influence of aerosols. In POMINO, the aerosol
 270 contribution is separated from that of the clouds, resulting in a lower CRF than for
 271 DOMINO. The CRF differs insignificantly between POMINO and POMINO v1.1,
 272 because the same AOD and other non-aerosol ancillary parameters are used in the
 273 retrieval process. Using the CRF from POMINO instead of DOMINO or QA4ECV for
 274 cloud screening means that the number of “valid” pixels in DOMINO increases by
 275 about 25%, particularly because much more pixels with high pollutant (aerosol and NO_2)

276 loadings are now included. This potentially reduces the sampling bias (Lin et al., 2014b,
277 2015), and the ensemble of pixels now includes scenes with high “aerosol radiative
278 fractions”. Further research is needed to fully understand how much these high-aerosol
279 scenes may be subject to the same screening issues as the cloudy scenes. Nevertheless,
280 the limited evidence here and in Lin et al. (2014b, 2015) suggests that including these
281 high-aerosol scenes does not affect the accuracy of NO₂ retrieval.

282 2.4 MAX-DOAS data

283 We use MAX-DOAS measurements at three suburban or urban sites in East China,
284 including one urban site at the Institute of Atmospheric Physics (IAP) in Beijing
285 (116.38° E, 39.38 ° N), one suburban site in Xianghe County (116.96° E, 39.75 ° N)
286 to the south of Beijing, and one urban site in the Wuxi City (120.31° E, 31.57 ° N) in
287 the Yangzi River delta (YRD). Figure 1 shows the locations of these sites overlaid with
288 POMINO v1.1 NO₂ VCDs in August 2012. Table 1 summarizes the information of
289 MAX-DOAS measurements.

290 The instruments in IAP and in Xianghe were designed at BIRA-IASB (Clémer et al.,
291 2010). Such an instrument is a dual-channel system composed of two thermally
292 regulated grating spectrometers, covering the ultraviolet (300–390 nm) and visible
293 (400–720 nm) wavelengths. It measures scattered sunlight every 15 minutes at nine
294 elevation angles: 2° , 4° , 6° , 8° , 10° , 12° , 15° , 30° , and 90° . The telescope
295 of the instrument is pointed to the north. The data are analyzed following Hendrick et
296 al. (2014). The Xianghe suburban site is influenced by pollution from the surrounding
297 major cities like Beijing and Tianjin. At Xianghe, MAX-DOAS data are data are
298 continuously available since early 2011, and data in 2012 are used here for comparison
299 with OMI products. At IAP, MAX-DOAS data are available in 2008 and 2009 (Table
300 1), thus for comparison purposes we process OMI products to match the MAX-DOAS
301 times.

302 Located on the roof of an 11-story building, the instrument at Wuxi was developed by
303 Anhui Institute of Optics and Fine Mechanics (AIOFM) (Wang et al., 2015, 2017a). Its
304 telescope is pointed to the north and records at five elevation angles (5° , 10° , 20° , 30° ,
305 and 90°). Wuxi is a typical urban site affected by heavy NO_x and aerosol pollution. The
306 measurements used here are analyzed in Wang et al. (2017a). Data are available in 2012
307 for comparison with OMI products.

308 When comparing the four OMI products against MAX-DOAS observations, temporal
309 and spatial inconsistency in sampling is inevitable. The spatial inconsistency, together
310 with the substantial horizontal inhomogeneity in NO_2 , might be more important than
311 the influence of temporal inconsistency (Wang et al., 2017b). The influence of the
312 horizontal inhomogeneity was suggested to be about 10–30% for MAX-DOAS
313 measurements in Beijing (Lin et al., 2014b; Ma et al., 2013) and 10–15% for less
314 polluted locations like Tai'an, Mangshan and Rudong (Irie et al., 2012). Following
315 previous studies, we average MAX-DOAS data within 1 h of the OMI overpass time,
316 and we select OMI pixels within 25 km of a MAX-DOAS site whose viewing zenith
317 angle is below 30° . To exclude local pollution events near the MAX-DOAS site (such
318 as the abrupt increase of NO_2 caused by the pass of consequent vehicles during a very
319 short period), the standard deviation of MAX-DOAS data within 1 h should not exceed
320 20% of their mean value (Lin et al., 2014b). We elect not to spatially average the OMI
321 pixels because they can reflect the spatial variability in NO_2 and aerosols.

322 We further exclude MAX-DOAS data in cloudy conditions, as clouds can cause large
323 uncertainties in MAX-DOAS and OMI data. To find the actual cloudy days, we use
324 MODIS/Aqua cloud fraction data, MODIS/Aqua Level-3 corrected reflectance (true
325 color) data at the $1^\circ \times 1^\circ$ resolution, and current weather data observed from the
326 nearest ground meteorological station (indicated by the black triangles in Fig. 1b).
327 Since there is only one meteorological station available near the Beijing area, it is used

328 for both IAP and Xianghe MAX-DOAS sites. We first use MODIS/Aqua corrected
329 reflectance (true color) to distinguish clouds from haze. For cloudy days determined by
330 the reflectance checking, we examine both the MODIS/Aqua cloud fraction data and
331 the meteorological station cloud records, considering that MODIS/Aqua cloud fraction
332 data may be missing or have a too coarse horizontal resolution to accurately interpret
333 the cloud conditions at the MAX-DOAS site. We exclude MAX-DOAS NO₂ data if the
334 MODIS/Aqua cloud fraction is larger than 60% and the meteorological station reports
335 a “BROKEN” (cloud fraction ranges from 5/8 to 7/8) or “OVERCAST” (full cloud
336 cover) sky. For the three MAX-DOAS sites together, this leads to 49 days with valid
337 data out of 64 days with pre-screening data.

338 We note here that using cloud fraction data from MODIS/Aqua or MAX-DOAS (for
339 Xianghe only, see Gielen et al., 2014) alone to screen cloudy scenes may not be
340 appropriate on heavy-haze days. For example, on 8th January, 2012, MODIS/Aqua
341 cloud fraction is about 70–80% over the North China Plain and MAX-DOAS at
342 Xianghe suggests the presence of “thick clouds”. However, both the meteorological
343 station and MODIS/Aqua corrected reflectance (true color) product suggest that the
344 North China Plain was covered by a thick layer of haze. Consequently, this day was
345 excluded from the analysis.

346 **3. Monthly climatology of aerosol extinction profiles from CALIOP and GEOS-** 347 **Chem**

348 3.1 CALIOP monthly climatology

349 The aerosol layer height (ALH) is a good indicator to what extent aerosols are mixed
350 vertically (Castellanos et al., 2015). As defined in Eq. A1 in Appendix B, the ALH is
351 the average height of aerosols weighted by vertically resolved aerosol extinction. Figure
352 2a shows the spatial distribution of our CALIOP ALH climatology in each season. At

353 most places, the ALH reaches a maximum in spring or summer and a minimum in fall
354 or winter. The lowest ALH in fall and winter can be attributed to heavy near-surface
355 pollution and weak vertical transport. The high values in summer are related to strong
356 convective activities. Over the north, the high values in spring are partly associated with
357 Asian dust events, due to high surface winds and dry soil in this season (Huang et al.,
358 2010; Proestakis et al., 2017; Wang et al., 2010), which also affects the oceanic regions
359 via atmospheric transport. The springtime high ALH over the south may be related to
360 the transport of carbonaceous aerosols from Southeast Asian biomass burning (Jethva
361 et al., 2016). Averaged over the domain, the seasonal mean ALHs are 1.48 km, 1.43
362 km, 1.27km, 1.18 km in spring, summer, fall and winter.

363 Figure 3a,b further shows the climatological monthly variations of ALH averaged over
364 Northern East China (the anthropogenic source region shown in orange in Fig. 1a) and
365 Northwest China (the dust source region shown in yellow in Fig. 1a). The two regions
366 exhibit distinctive temporal variations. Over Northern East China, the ALH reaches a
367 maximum in April (~1.53 km) and a minimum in December (~1.14 km). Over
368 Northwest China, the ALH peaks in August (~1.59km) because of strongest convection
369 (Zhu et al., 2013), although the springtime ALH is also high.

370 Figure 4a shows the climatological seasonal regional average vertical profiles of aerosol
371 extinction over Northern East China. Here, the aerosol extinction increases from the
372 ground level to a peak at about 300–600 m (season dependent), above which it
373 decreases gradually. The height of peak extinction is lowest in winter, consistent with
374 a stagnant atmosphere, thin mixing layer, and increased emissions (from residential and
375 industrial sectors). The large error bars (horizontal lines in different layers, standing for
376 1 standard deviation) indicate strong spatiotemporal variability of aerosol extinction.

377 Over Northwest China (Fig. 5a), the column total aerosol extinction is much smaller
378 than that over Northern East China (Fig. 4a), due to lower anthropogenic sources and

379 dominant natural dust emissions. Vertically, the decline of extinction from the peak-
380 extinction height to 2 km is also much more gradual than the decline over Northern East
381 China, indicating stronger lifting of surface emitted aerosols. In winter, the column total
382 aerosol extinction is close to the high value in dusty spring, whereas the vertical
383 gradient of extinction is strongest among the seasons. This reflects the high
384 anthropogenic emissions in parts of Northwest China, which have been rapidly
385 increasing in the 2000s due to relatively weak emission control supplemented by
386 growing activities of relocation of polluted industries from the eastern coastal regions
387 (Cui et al., 2016; Zhao et al., 2015).

388 Overall, the spatial and seasonal variations of CALIOP aerosol vertical profiles are
389 consistent with changes in meteorological conditions, anthropogenic sources, and
390 natural emissions. The data will be used to evaluate and adjust GEOS-Chem simulation
391 results in Sect. 3.2. A comparison of our CALIOP dataset with NASA's official Level-
392 3 data is presented in Appendix C.

393 3.2 Evaluation of GEOS-Chem aerosol extinction profiles

394 Figure 2b shows the spatial distribution of seasonal ALHs simulated by GEOS-Chem.
395 The model captures the spatial and seasonal variations of CALIOP ALH (Fig. 2a) to
396 some degree, with an underestimate by about 0.3 km on average. The spatial
397 correlation between CALIOP (Fig. 2a) and GEOS-Chem (Fig. 2b) ALH is 0.37 in
398 spring, 0.57 in summer, 0.40 in fall, and 0.44 in winter. The spatiotemporal consistency
399 and underestimate is also clear from the regional mean monthly ALH data in Fig. 3 –
400 the temporal correlation between GEOS-Chem and CALIOP ALH is 0.90 in Northern
401 East China and 0.97 in Northwest China.

402 Figures 4a and 5a show the GEOS-Chem simulated 2007–2015 monthly climatological
403 vertical profiles of aerosol extinction coefficient over Northern East China and

404 Northwest China, respectively. Over Northern East China (Fig. 4a), the model (red line)
405 captures the vertical distribution of CALIOP extinction (black line) below the height of
406 1 km, despite a slight underestimate in the magnitude of extinction and an overestimate
407 in the peak-extinction height. From 1 to 5 km above the ground, the model substantially
408 overestimates the rate of decline in extinction coefficient with increasing altitude.
409 Across the seasons, GEOS-Chem underestimates the magnitude of aerosol extinction
410 by up to 37% (depending on the height). Over Northwest China (Fig. 5a), GEOS-Chem
411 has an underestimate in all seasons, with the largest bias by about 80% in winter likely
412 due to underestimated water-soluble aerosols and dust emissions (Li et al., 2016; Wang
413 et al., 2008a).

414 Since the POMINO v1.1 algorithm uses MODIS AOD to adjust model AOD, it only
415 uses the CALIOP aerosol extinction profile shape to adjust the modeled shape (Eqs. 1
416 and 2). Figures 4b and 4b show the vertical shapes of aerosol extinction, averaged
417 across all profiles in each season over Northern East China and Northwest China,
418 respectively. Over Northern East China (Fig. 4b), GEOS-Chem underestimates the
419 CALIOP values above 1 km by 52–71%. This underestimate leads to a lower ALH,
420 consistent with the finding by van Donkelaar et al. (2013) and Lin et al. (2014b). Over
421 Northwest China (Fig. 5b), the model also underestimates the CALIOP values above 1
422 km by 50–62%. These results imply the importance of correcting the modeled aerosol
423 vertical shape prior to cloud and NO₂ retrievals.

424 **4. Effects of aerosol vertical profile improvement on cloud retrieval in 2012**

425 Figure 6a, b shows the monthly average ALH and cloud top height (CTH,
426 corresponding to cloud pressure, CP) over Northern East China and Northwest China
427 in 2012. In order to discuss the CTH, only cloudy days are analyzed here, by excluding
428 days with zero cloud fraction (CF = 0, clear-sky cases) in POMINO. Although “clear
429 sky” is used sometimes in the literature to represent low cloud coverage (e.g., CF < 0.2

430 or $CRF < 0.5$, Boersma et al., 2011; Chimot et al., 2016), here it strictly means $CF = 0$
431 while “cloudy sky” means $CF > 0$. About 62.7% of days contain non-zero fractions of
432 clouds over Northern East China, and the number is 59.1% for Northwest China. The
433 CF changes from POMINO to POMINO v1.1 (i.e., after aerosol vertical profile
434 adjustment) are negligible (within $\pm 0.5\%$, not shown) due to the same values of AOD
435 and SSA used in both products. This is because overall CF is mostly driven by the
436 continuum reflectance at 475 nm (mainly determined by AOD and surface reflectance,
437 which remain unchanged), which is insensitive of aerosol profile but CTH is driven by
438 the O_2-O_2 SCD, which is itself impacted by ALH.

439 Figure 6a, b shows that over the two regions, the CTH varies notably from one month
440 to another, whereas the ALH is much more stable across the months. Over Northern
441 East China, the ALH increases by 0.52 km from POMINO (orange dashed line) to
442 POMINO v1.1 (orange solid line) due to the CALIOP-based monthly climatological
443 adjustment. The increase in ALH means a stronger “shielding” effect of aerosols on the
444 O_2-O_2 absorbing dimer, which, in turn, results in a reduced CTH by 0.69 km on average.
445 For POMINO over Northern East China (Fig. 6a), the retrieved clouds usually extend
446 above the aerosol layer, i.e., the CTH (grey dashed line) is much larger than the ALH
447 (orange dashed line). Using the CALIOP climatology in POMINO v1.1 results in the
448 ALH higher than the CTH in fall and winter. The more elevated ALH is consistent with
449 the finding of Jethva et al. (2016) that a significant amount of absorbing aerosols resides
450 above clouds over Northern East China based on 11-year (2004–2015) OMI near-UV
451 observations.

452 The CTH in Northwest China is much lower than in Northern East China (Fig. 6a versus
453 7b). This is because the dominant type of actual clouds is (optically thin) cirrus over
454 western China (Wang et al., 2014), which is interpreted by the O_2-O_2 cloud retrieval
455 algorithm as reduced CTH (with cloud base from the ground). The reduction in CTH

456 from POMINO to POMINO v1.1 over Northwest China is also smaller than the
457 reduction over Northern East China, albeit with a similar enhancement in ALH, due to
458 lower aerosol loadings (Fig. 6c versus 6d).

459 Figure 7g,h presents the relative change in CP from POMINO to POMINO v1.1 as a
460 function of AOD (binned at an interval of 0.1) and changes in ALH from POMINO to
461 POMINO v1.1 (Δ ALH, binned every 0.2 km) across all pixels in 2012 over Northern
462 East China. Results are separated for low cloud fraction ($CF < 0.05$ in POMINO, Fig.
463 7g) and modest cloud fraction ($0.2 < CF < 0.3$, Fig. 7h). The median of the CP changes
464 for pixels within each AOD and Δ ALH bin is shown. Figure 7e,f presents the
465 corresponding numbers of occurrence under the two cloud conditions.

466 Figure 7 shows that over Northern East China, the increase in ALH is typically within
467 0.6 km for the case of $CF < 0.05$ (Fig. 7e), and the corresponding increase in CP is
468 within 6% (Fig. 7g). In this case, the average CTH (2.95 km in POMINO versus 1.58
469 km in POMINO v1.1) becomes much lower than the average ALH (1.06 km in
470 POMINO versus 1.98 km in POMINO v1.1). For the case with CF between 0.2 and 0.3,
471 the increase in ALH is within 1.2 km for most scenes (Fig. 7f), which leads to a CP
472 change of 2% (Fig. 7h), much smaller than the CP change for $CF < 0.05$ (Fig. 7g). This
473 is partly because the larger the CF is, the smaller a change in CF is required to
474 compensate for the Δ ALH in the O_2-O_2 cloud retrieval algorithm. Furthermore, with
475 $0.2 < CF < 0.3$, the mean value of CTH is much higher than ALH in both POMINO
476 (2.76 km for CTH versus 1.13km for ALH) and POMINO v1.1 (2.60km for CTH versus
477 2.09 km for ALH), thus a large portion of clouds are above aerosols so that the change
478 in CP is less sensitive to Δ ALH. We find that the summertime data contribute the
479 highest portion (36.5%) to the occurrences for $0.2 < CF < 0.3$.

480 For Northwest China (not shown), the dependence of CP changes to AOD and Δ ALH
481 is similar to that for Northern East China. In particular, the CP change is within 10%
482 on average for the case of $CF < 0.05$ and 1.5% for the case of $0.2 < CF < 0.3$.

483 **5. Effects of aerosol vertical profile improvement on NO₂ retrieval in 2012**

484 Figure 7a presents the percentage changes in clear-sky NO₂ VCD from POMINO to
485 POMINO v1.1 as a function of binned AOD and Δ ALH over Northern East China. Here,
486 clear-sky pixels are chosen based on $CF = 0$ in POMINO. In any AOD bin, an increase
487 in Δ ALH leads to an enhancement in NO₂. And for any Δ ALH, the change in VCD is
488 greater (smaller) when AOD becomes larger (smaller), which indicates that the NO₂
489 retrieval is more sensitive to ALH in high aerosol loading cases. Clearly, the change in
490 NO₂ is not a linear function of AOD and Δ ALH.

491 For cloudy scenes (Fig. 7b,c, cloud data are based on POMINO), the change in NO₂
492 VCD is less sensitive to AOD and Δ ALH. This is because the existence of clouds limits
493 the optical effect of aerosols on tropospheric NO₂. Figure 6a presents the nitrogen layer
494 height (NLH, defined as the average height of model simulated NO₂ weighted by its
495 volume mixing ratio in each layer) in comparison to the ALH and CLH over Northern
496 East China. The figure shows that the POMINO v1.1 CTH is higher than the NLH in
497 all months and higher than the ALH in warm months, which means a “shielding” effect
498 on both NO₂ and aerosols.

499 Over Northwest China (not shown), the changes in clear-sky NO₂ VCD are within 9%
500 for most cases, which are much smaller than over Eastern China (within 18%). This is
501 because the NLH is much higher than the CLH and ALH (Fig. 6b) in absence of surface
502 anthropogenic emissions.

503 We convert the valid pixels into monthly mean Level-3 values datasets on a 0.25° long.
504 $\times 0.25^\circ$ lat. grid. Figure 8a,b compares the seasonal spatial variations of NO₂ VCD in
505 POMINO v1.1 and POMINO in 2012. In both products, NO₂ peaks in winter due to the
506 longest lifetime and highest anthropogenic emissions (Lin, 2012). NO₂ also reaches a
507 maximum over Northern East China as a result of substantial anthropogenic sources.
508 From POMINO to POMINO v1.1, the NO₂ VCD increases by 3.4% (-67.5–41.7%) in
509 spring for the domain average (range), 3.0% (-59.5–34.4%) in summer, 4.6% (-15.3–
510 39.6%) in fall and 5.3% (-68.4–49.3%) in winter. The NO₂ change is highly dependent
511 on the location and season. The increase over Northern East China is largest in winter,
512 wherein the positive value for Δ ALH implies that elevated aerosol layers “shield” the
513 NO₂ absorption.

514 **6. Evaluating satellite products using MAX-DOAS data**

515 We use MAX-DOAS data, after cloud screening (Sect. 2.4), to evaluate DOMNO v2,
516 QA4ECV, POMINO and POMINO v1.1. The scatterplots in Fig. 9a-d compare the NO₂
517 VCDs from 162 OMI pixels on 49 days with their MAX-DOAS counterparts. The
518 statistical results are shown in Table 2 as well. Different colors differentiate the seasons.
519 The high values of NO₂ VCD ($> 30 \times 10^{15}$ molec. cm⁻²) occur mainly in fall (blue)
520 and winter (black). POMINO v1.1 and POMINO capture the day-to-day variability of
521 MAX-DOAS data, i.e., $R^2 = 0.80$ for both products. The normalized mean bias (NMB)
522 of POMINO v1.1 relative to MAX-DOAS data (-3.4%) is smaller than the NMB of
523 POMINO (-9.6%). Also, the reduced major axis (RMA) regression shows that the slope
524 for POMINO v1.1 (0.95) is closer to unity than the slope for POMINO (0.78). When
525 all OMI pixels in a day are averaged (Fig. 9e,f), the correlation across the total of 49
526 days further increase for both POMINO v1.1 ($R^2 = 0.89$) and POMINO ($R^2 = 0.86$),
527 whereas POMINO v1.1 still has a lower NMB (-3.7%) and better slope (0.96) than
528 POMINO (-10.4% and 0.82, respectively). These results suggest that correcting aerosol

529 vertical profiles, at least on a climatology basis, already leads to a significant improved
530 NO₂ retrieval from OMI.

531 Figure 9 show that DOMINO v2 is correlated with MAX-DOAS ($R^2 = 0.68$ in Fig. 9c
532 and 0.75 in Fig. 9g) but not as strong as POMINO and POMINO v1.1 for all days. The
533 discrepancy between DOMINO v2 and MAX-DOAS is particularly large for very high
534 NO₂ values ($> 70 \times 10^{15}$ molec. cm⁻²). The R^2 for QA4ECV (0.75 in Fig. 9d and 0.82
535 in Fig. 9h) is slightly better than DOMINO, but the NMB is higher (-22.0% and -22.7%)
536 and the slope drops to 0.66 . These results are consistent with the finding of Lin et al.
537 (2014b, 2015) that explicitly including aerosol optical effects improves the NO₂
538 retrieval.

539 Table 3 further shows the comparison statistics for 11 haze days. The haze days are
540 determined when both the ground meteorological station data and MODIS/Aqua
541 corrected reflectance (true color) data indicate a haze day. The table also lists AOD,
542 SSA, CF and MAX-DOAS NO₂ VCD, as averaged over all haze days. A large amount
543 of absorbing aerosols occurs on these haze days ($AOD = 1.13$, $SSA = 0.90$). The
544 average MAX-DOAS NO₂ VCD reaches 51.9×10^{15} molec. cm⁻². Among the four
545 satellite products, POMINO v1.1 has the highest R^2 (0.76) and the lowest bias (4.4%)
546 with respect to MAX-DOAS, whereas DOMINO v2 and QA4ECV reproduce the
547 variability to a limited extent ($R^2 = 0.38$ and 0.34 , respectively). This is consistent with
548 the previous finding that the accuracy of DOMINO v2 is reduced for polluted, aerosol-
549 loaded scenes (Boersma et al., 2011; Chimot et al., 2016; Kanaya et al., 2014; Lin et
550 al., 2014b).

551 Table 4 shows the comparison statistics for 18 cloud-free days ($CF = 0$ in POMINO,
552 and $AOD = 0.60$ on average). Here, POMINO v1.1, POMINO and DONIMO v2 do not
553 show large differences in R^2 (0.53 – 0.56) and NMB (20.8 – 29.4%) with respect to MAX-
554 DOAS. QA4ECV has a higher R^2 (0.63) and a lower NMB (-5.8%), presumably

555 reflecting the improvements in this (EU-) consortium approach, at least in mostly cloud-
556 free situations. However, the R^2 values for POMINO and POMINO v1.1 are much
557 smaller than the R^2 values in haze days, whereas the opposite changes are true for
558 DOMINO v2 and QA4ECV. Thus, for this limited set of data, the changes from
559 DOMINO v2 and QA4ECV to POMINO and POMINO v1.1 mainly reflect the
560 improved aerosol treatment in hazy scenes. Further research may use additional MAX-
561 DOAS datasets to evaluate the satellite products more systematically.

562 **7. Conclusions**

563 This paper improves upon our previous POMINO algorithm (Lin et al., 2015) to retrieve
564 the tropospheric NO_2 VCDs from OMI, by compiling a 9-year (2007–2015) CALIOP
565 monthly climatology of aerosol vertical extinction profiles to adjust GEOS-Chem
566 aerosol profiles used in the NO_2 retrieval process. The improved algorithm is referred
567 to as POMINO v1.1. Compared to monthly climatological CALIOP data over China,
568 GEOS-Chem simulations tend to underestimate the aerosol extinction above 1 km, as
569 characterized by an underestimate in ALH by 300–600 m (seasonal and location
570 dependent). Such a bias is corrected in POMINO v1.1 by dividing, for any month and
571 grid cell, the CALIOP monthly climatological profile by the model climatological
572 profile to obtain a scaling profile and then applying the scaling profile to model data in
573 all days of that month in all years.

574 The aerosol extinction profile correction leads to an insignificant change in CF from
575 POMINO to POMINO v1.1, since the AOD and surface reflectance are unchanged. In
576 contrast, the correction results in a notably increase in CP (i.e., a decrease in CTH), due
577 to lifting of aerosol layers. The CP changes are generally within 6% for scenes with low
578 cloud fraction ($\text{CF} < 0.05$ in POMINO), and within 2% for scenes with modest cloud
579 fraction ($0.2 < \text{CF} < 0.3$ in POMINO).

580 The NO₂ VCDs increase from POMINO to POMINO v1.1 in most cases due to lifting
581 of aerosol layers that enhances the “shielding” of NO₂ absorption. The NO₂ VCD
582 increases by 3.4% (-67.5–41.7%) in spring for the domain average (range), 3.0% (-
583 59.5–34.4%) in summer, 4.6% (-15.3–39.6%) in fall and 5.3% (-68.4–49.3%) in winter.
584 The NO₂ changes highly season and location dependent, and are most significant for
585 wintertime Northern East China.

586 Further comparisons with independent MAX-DOAS NO₂ VCD data for 162 OMI
587 pixels in 49 days show good performance of both POMINO v1.1 and POMINO in
588 capturing the day-to-day variation of NO₂ ($R^2=0.80$, $n=162$), compared to DOMINO
589 v2 ($R^2=0.67$) and the new QA4ECV product ($R^2=0.75$). The NMB is smaller in
590 POMINO v1.1 (-3.4%) than in POMINO (-9.6%), with a slightly better slope (0.804
591 versus 0.784). On hazy days with high aerosol loadings (AOD = 1.13 on average),
592 POMINO v1.1 has the highest R^2 (0.76) and the lowest bias (4.4%) whereas DOMINO
593 and QA4ECV have difficulty in reproducing the day-to-day variability in MAX-DOAS
594 NO₂ measurements ($R^2 = 0.38$ and 0.34 , respectively). The four products show small
595 differences in R^2 on clear-sky days (CF = 0 in POMINO, AOD = 0.60 on average),
596 among which QA4ECV shows a highest R^2 (0.63) and lowest NMB (-5.8%),
597 presumably reflecting the improvements in less polluted place such as Europe and the
598 US. Thus the explicit aerosol treatment (in POMINO and POMINO v1.1) and the
599 aerosol vertical profile correction (in POMINO v1.1) improves the NO₂ retrieval
600 especially in hazy cases.

601 The POMINO v1.1 algorithm is a core step towards our next public release of data
602 product, POMINO v2. The v2 product will contain a few additional updates, including
603 but not limited to using MODIS Collection 6 Merged 10-km Level-2 AOD data that
604 combine the Dark Target (Levy et al., 2013) and Deep Blue (Sayer et al., 2014) products,
605 as well as MODIS MCD43C2 Collection 6 daily BRDF data. Meanwhile, the POMINO

606 algorithm framework is being applied to the recently launched TropOMI instrument
607 that provides NO₂ information at a much higher spatial resolution (3.5 x 7 km²). A
608 modified algorithm can also be used to retrieve sulfur dioxide, formaldehyde and other
609 trace gases from TropOMI, for which purposes our algorithm will be available to the
610 community on a collaborative basis. Future research can correct the SSA and NO₂
611 vertical profile to further improve the retrieval algorithm, and can use more
612 comprehensive independent data to evaluate the resulting satellite products.

615 (41775115), the 973 program (2014CB441303), the Chinese Scholarship Council, and
616 the EU FP7 QA4ECV project (grant no. 607405).

617 **Appendix A: Introduction to the QA4ECV product**

618 The QA4ECV NO₂ product (<http://www.qa4ecv.eu/>) builds on a (EU-) consortium
619 approach to retrieve NO₂ from GOME, SCIAMACHY, GOME-2, and OMI. The main
620 contributions are provided by BIRA-IASB, the University of Bremen (IUP), MPIC,
621 KNMI, and Wageningen University. Uncertainties in spectral fitting for NO₂ SCDs and
622 in AMF calculations were evaluated by Zara et al. (2018) and Lorente et al. (2017),
623 respectively. QA4ECV contains improved SCD NO₂ data (Zara et al., 2018). Our test
624 suggests that using the QA4ECV SCD data instead of DOMINO SCD data would
625 reduce the underestimate against MAX-DOAS VCD data from 3.7% to 0.2%, a relative
626 minor improvement. Lorente et al., (2017) showed that across the above algorithms,
627 there a structural uncertainty by 42% in the NO₂ AMF calculation over polluted areas.
628 By comparing to our POMINO product, Lorente et al. also showed that the choice of
629 aerosol correction may introduce an additional uncertainty by up to 50% for situations
630 with high polluted cases, consistent with Lin et al. (2014b, 2015) and the findings here.

631 For a complete description of the QA4ECV algorithm improvements, and quality
632 assurance, please see Boersma et al. (2018).

633 **Appendix B: Constructing the CALIOP monthly climatology of aerosol extinction** 634 **vertical profile**

635 Our use the all-sky Level-2 CALIOP data to construct the Level-3 monthly climatology.
636 We choose the all-sky product instead of clear-sky data, since previous studies indicate
637 that the climatological aerosol extinction profiles are affected insignificantly by the
638 presence of clouds (Koffi et al., 2012; Winker et al., 2013). As we use this
639 climatological data to adjust GEOS-Chem results, choosing all-sky data improves
640 consistency with the model simulation when doing the daily correction.

641 To select valid pixels, we follow the data quality criteria by Winker et al., (2013) and
642 Amiridis et al., (2015). Only the pixels with Cloud Aerosol Discrimination (CAD)
643 scores between -20 and -100 with extinction Quality Control (QC) flag valued at 0, 1,
644 18, and 16 are selected. We further discard samples with an extinction uncertainty of
645 99.9 km^{-1} , which is indicative of unreliable retrieval. We only accept extinction values
646 falling in the range from 0.0 to 1.25, according to CALIOP observation thresholds.
647 Previous studies showed that weakly scattering edges of icy clouds are sometimes
648 misclassified as aerosols (Winker et al., 2013). To eliminate contamination from icy
649 clouds we exclude the aerosol layers above the cloud layer (with layer-top temperature
650 below $0 \text{ }^{\circ}\text{C}$) when both of them are above 4km (Winker et al., 2013).

651 After the pixel-based screening, we aggregate the CALIOP data at the model grid
652 (0.667° long. x 0.5° lat.) and vertical resolution (47 layers, with 36 layers or so in the
653 troposphere). For each grid cell, we choose the CALIOP pixels within 1.5° of the grid
654 cell center. CALIOP Level-2 data are always presented at the fixed 399 altitudes above
655 sea level. To account for the difference in surface elevation between a CALIOP pixel

656 and the respective model grid cell, we convert the altitude of the pixel to a height above
657 the ground, by using the surface elevation data provided in CALIOP. We then average
658 horizontally and vertically the profiles of all pixels within one model grid cell and layer.
659 We do the regridding day-by-day for all grid cells to ensure that GEOS-Chem and
660 CALIOP extinction profiles are coincident spatially and temporally. Finally, we
661 compile a monthly climatological dataset by averaging over 2007–2015.

662 Figure A1 shows the number of aerosol extinction profiles in each grid cell and 12×9
663 = 108 months that are used to compile the CALIOP climatology, both before and after
664 data screening. Table A1 presents additional information on monthly and yearly bases.
665 On average, there are 165 and 47 aerosol extinction profiles per month per grid cell
666 before and after screening, respectively. In the final 9-year monthly climatology, each
667 grid cell has about 420 aerosol extinction profiles on average, about 28% of the prior-
668 screening profiles. Figure A1 shows that the number of valid profiles decreases sharply
669 over the Tibet Plateau and at higher latitudes ($> 43^\circ \text{ N}$) due to complex terrain and
670 icy/snowy ground.

671 As discussed above, we choose the CALIOP pixels within 1.5° of a grid cell center.
672 We test this choice by examining the aerosol layer height (ALH) produced for that grid
673 cell. The ALH is defined as the extinction-weighted height of aerosols (see Eq. A1,
674 where n denotes the number of tropospheric layers, ε_i the aerosol extinction at layer
675 i , and H_i the layer center height above the ground). We find that choosing pixels
676 within 1.0° of a grid cell center leads to a noisier horizontal distribution of ALH, owing
677 to the small footprint of CALIOP. On the other hand, choosing 2.0° leads to a too
678 smooth spatial gradient of ALH with local characteristics of aerosol vertical
679 distributions are largely lost. We thus decide that 1.5° is a good balance between noise
680 and smoothness.

$$681 \quad \text{ALH} = \frac{\sum_{i=1}^{i=n} \varepsilon_i H_i}{\sum_{i=1}^{i=n} \varepsilon_i} \quad (\text{A1})$$

682 Certain grid cells do not contain sufficient valid observations for some months of the
 683 climatological dataset. We fill in missing monthly values of a grid cell using valid data
 684 in the surrounding $5 \times 5 = 25$ grid cells (within ~ 100 km). If the 25 grid cells do not
 685 have enough valid data, we use those in the surrounding $7 \times 7 = 49$ grid cells (within \sim
 686 150 km). A similar procedure is used by Lin et al. (2014b, 2015) to fill in missing values
 687 in the gridded MODIS AOD dataset.

688 For each grid cell in each month, we further correct singular values in the vertical profile.
 689 In a month, if a grid cell i has an ALH outside $\text{mean} \pm 1 \sigma$ of its surrounding 25 or 49
 690 grid cells, we select i 's surrounding grid cell j whose ALH is the median of i 's
 691 surrounding grid cells, and use j 's profile to replace i 's. Whether 25 or 49 surrounding
 692 grid cells are chosen depends on the number of valid pixels shown in Fig. A1b. If the
 693 number of valid pixels in i is below $\text{mean} - 1 \sigma$ of all grid cells in the whole domain,
 694 which is often the case for Tibetan grid cells, we use i 's surrounding 49 grid cells;
 695 otherwise we use i 's surrounding 25 grid cells.

696 **Appendix C. Comparing our and NASA's CALIOP monthly climatology**

697 We compare our gridded climatological profiles to NASA CALIOP Version 3 Level-3
 698 all-sky monthly profiles at 532 nm (Winker et al., 2013). The NASA Level-3 data has
 699 a horizontal resolution of $2^\circ \text{ lat.} \times 5^\circ \text{ lon.}$ and a vertical resolution of 60 m (from -0.5
 700 to 12 km above sea level). We combine NASA monthly data over 2007–2015 to
 701 construct a monthly climatology for comparison with our own compilation. We only
 702 choose aerosol extinction data in the troposphere with error less than 0.15 (the valid
 703 range given in the CALIOP dataset). If the number of valid monthly profiles in a grid
 704 cell is less than five (i.e., for the same month in five out of the nine years), then we
 705 exclude data in that grid cell; see the dark gray grid cells in Fig. 2c.

706 Several methodological differences exist between generating our and NASA CALIOP
707 datasets. First, the two datasets have different horizontal resolutions. Also, we sample
708 all valid CALIOP pixels within 1.5° of a grid cell center, whereas the NASA dataset
709 samples all valid pixels within a grid cell. Besides, our CALIOP dataset involves
710 several steps of horizontal interpolation, for purposes of subsequent cloud and NO_2
711 retrievals, which is not done in the NASA dataset. In addition, we match CALIOP data
712 vertically to the GEOS-Chem vertical resolution, whereas the NASA dataset maintains
713 the original resolution.

714 Figure 2c shows the spatial distribution of ALH in all seasons based on NASA CALIOP
715 Level-3 all-sky monthly climatology. The horizontal resolution of NASA data is much
716 coarser than ours; and NASA data are largely missing over the southwest with complex
717 terrains. We choose to focus on the comparison over East China (the black box in Fig.
718 1a). Over East China, the two climatology datasets generally exhibit similar spatial
719 patterns of ALH in all seasons (Fig. 2a, c). The NASA dataset suggests higher ALHs
720 than ours over Eastern China, especially in summer, due mainly to differences in the
721 sampling and regriding processes. Figure 3c further compares the monthly variation
722 of ALH between our (black line with error bars) and NASA (blue filled triangles)
723 datasets averaged over East China. The two datasets are consistent in almost all months,
724 indicating that their regional differences are largely smoothed out by spatial averaging.

1008

1009

Table A1. Number of CALIOP observations in a grid cell ($0.667^0 \times 0.5^0$).

	Before filtering				After filtering			
	Mean	Median	Minima	Maximum	Mean	Median	Minima	Maximum
For a month	165	169	0	291	47	39	0	223
For the same month in nine years	1483	1513	192	1921	420	395	0	1548
For all months in nine years	17794	18528	5608	20781	5033	5381	146	12650

1010

Table 1. MAX-DOAS measurement sites and corresponding meteorological stations.

MAX-DOAS site name	Site information	Measurement times	Corresponding meteorological station name	Meteorological station information
Xianghe	116.96°E, 39.75°N, 36 m, suburban	2012/01/01 -2012/12/31	CAPITAL INTERNATIONAL	116.89°E, 40.01°N, 35.4 m
IAP	116.38°E, 39.98°N, 92 m, urban	2008/06/22 -2009/04/16	CAPITAL INTERNATIONAL	116.89°E, 40.01°N, 35.4 m
Wuxi	120.31°E, 31.57°N, 20 m, urban	2012/01/01 -2012/12/31	HONGQIAO INTL	121.34°E, 31.20°N, 3 m

1011

Table 2. Pixel-based evaluation of OMI NO₂ products with respect to MAX-DOAS for 162 pixels on 49 days.

	POMINO v1.1	POMINO	DOMINO v2	QA4ECV
Slope	0.95	0.78	1.06	0.66
Intercept (10 ¹⁵ molec. cm ⁻²)	-1.00	0.96	-3.86	1.09
R ²	0.80	0.80	0.68	0.75
NMB (%)	-3.4	-9.6	-2.1	-22.0

1012

1013

Table 3. Pixel-based evaluation of OMI NO₂ products with respect to MAX-DOAS for 27 pixels on 11 haze days¹.

	POMINO v1.1	POMINO	DOMINO v2	QA4ECV
Slope	1.07	0.80	1.11	0.58
Intercept (10 ¹⁵ molec. cm ⁻²)	-3.58	1.76	-11.79	3.20
R ²	0.76	0.68	0.38	0.34
NMB (%)	4.4	-9.4	-5.0	-26.1

1014 1. The haze days are determined when the ground meteorological station data and
1015 MODIS/Aqua corrected reflectance (true color) data both indicate a haze day.
1016 Average across the pixels, AOD = 1.13 (median = 1.10), SSA = 0.90 (0.91), MAX-
1017 DOAS NO₂ = 51.92 x 10¹⁵ molec. cm⁻², and CF = 0.06 (0.03).

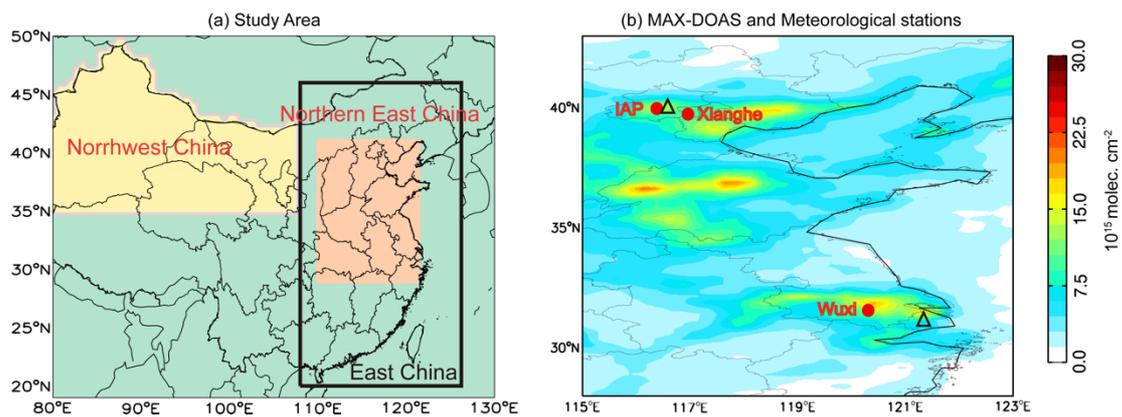

Table 4. Evaluation of OMI NO₂ products with respect to MAX-DOAS of 36 pixels on 18 cloud-free days¹.

	POMINO v1.1	POMINO	DOMINO v2	QA4ECV
Slope	1.30	1.13	0.92	0.79
Intercept (10 ¹⁵ molec. cm ⁻²)	-0.61	0.31	2.32	1.05
R ²	0.55	0.56	0.53	0.63
NMB (%)	29.4	20.8	21.9	-5.8

1018 1. CF=0 in POMINO product. Average across the pixels, AOD = 0.60 (median = 0.47),
1019 SSA = 0.90 (0.91), and MAX-DOAS NO₂ = 26.82 x 10¹⁵ molec. cm⁻².

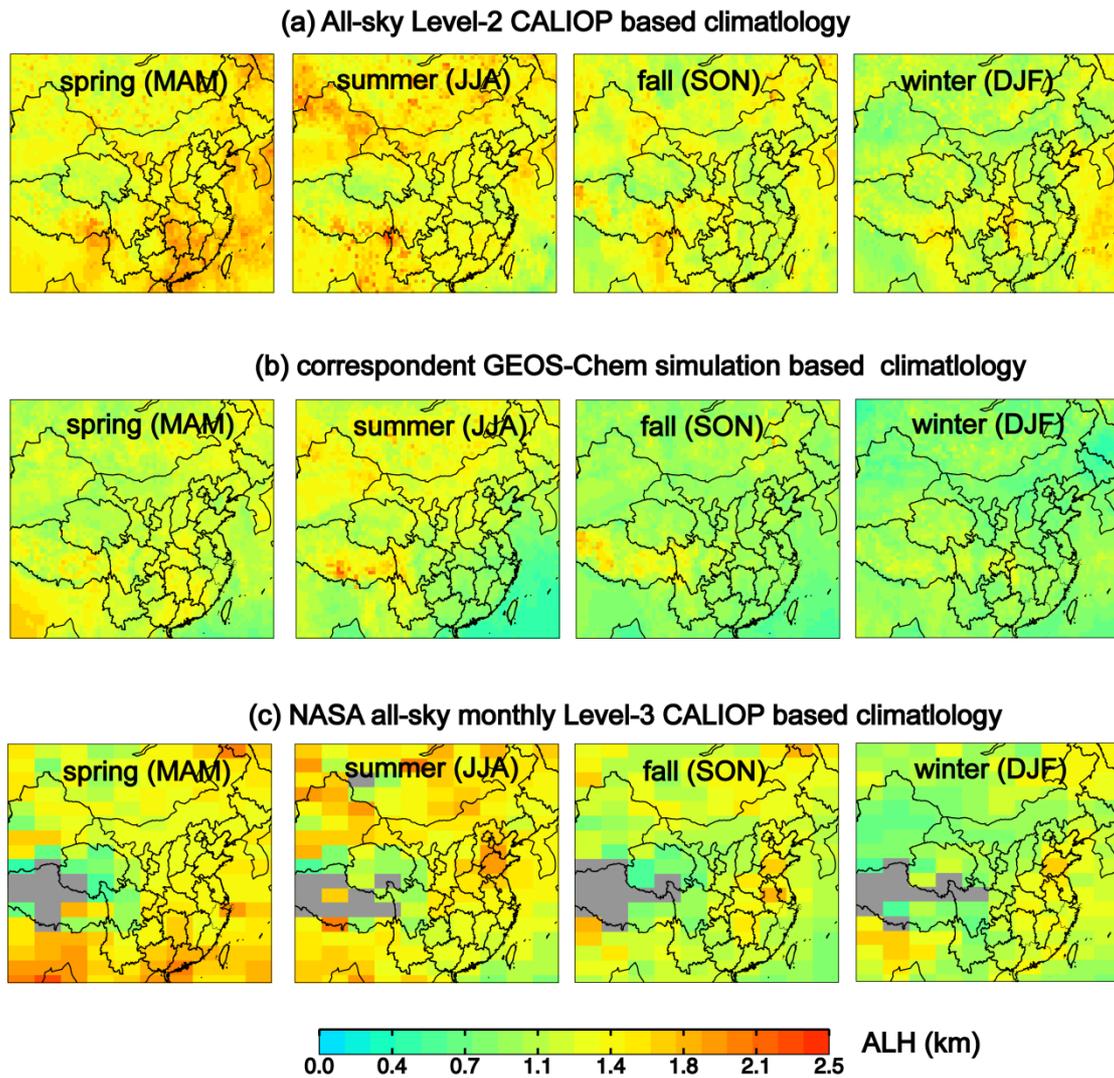

1020 Figure A1. The total number of CALIOP Level-2 aerosol extinction profiles at 532 nm
 1021 used to derive our climatological (2007–2015) dataset on a 0.667° long. \times 0.5° lat.
 1022 grid (a) before and (b) after filtering.

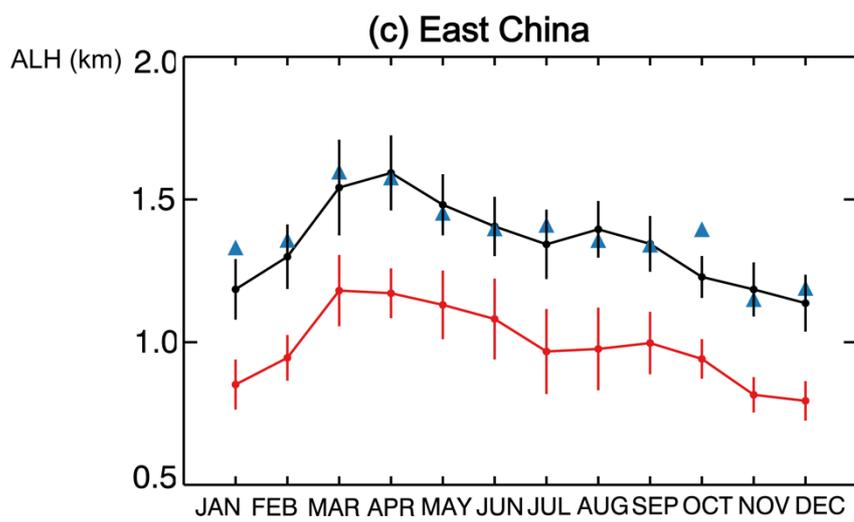

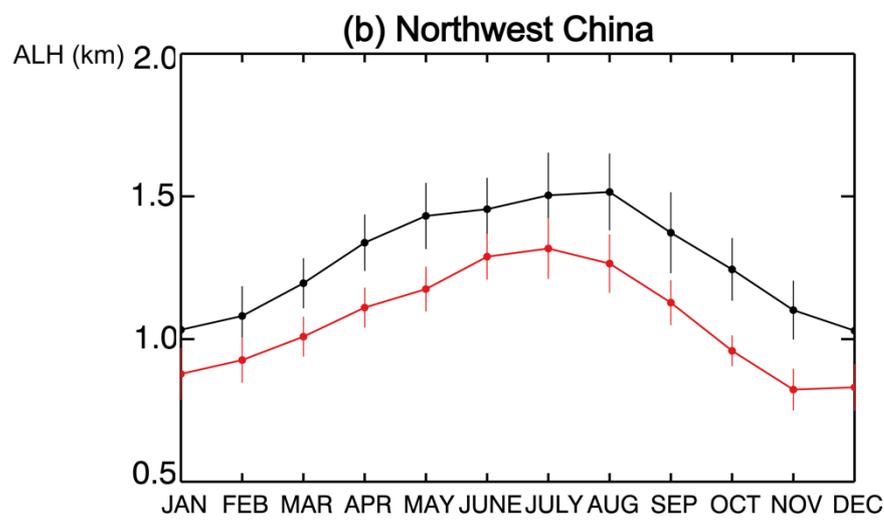

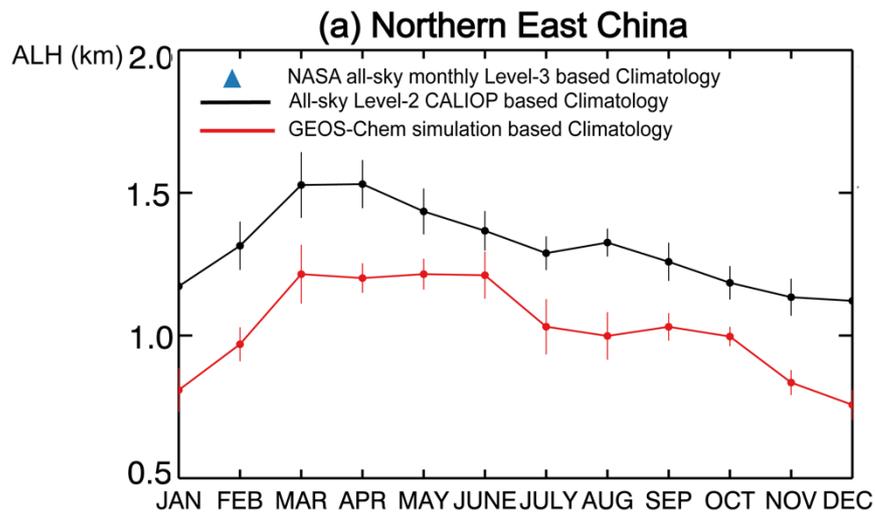

1023 Figure 1. (a) Three study areas: Northern East China, Northwest China, and East China.

1024 (b) MAX-DOAS measurement sites (red dots) and corresponding meteorological

1025 stations (black triangle) overlaid on POMINO v1.1 NO₂ VCDs in August 2012.

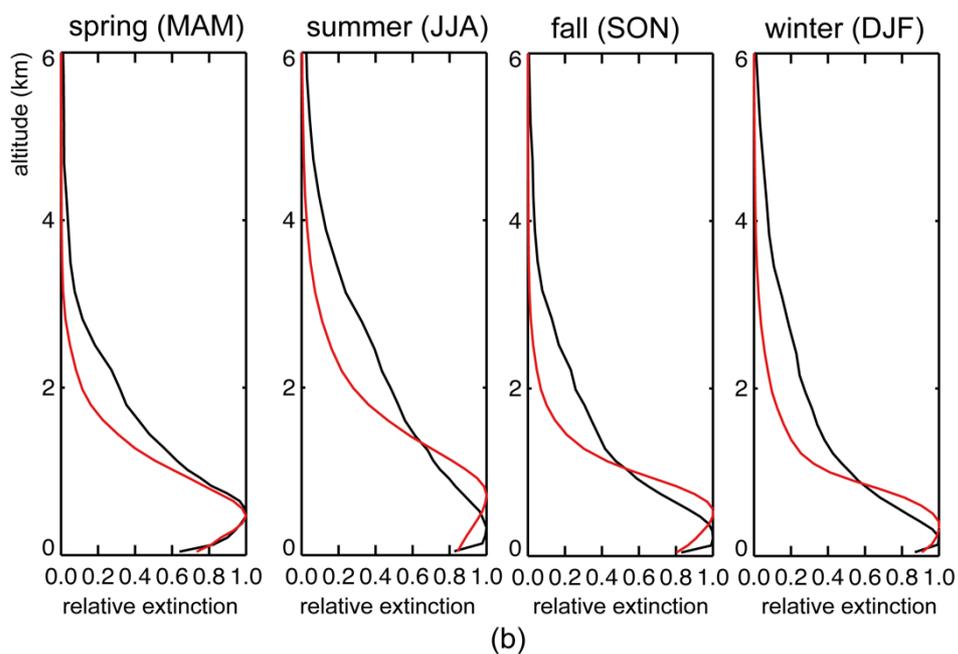

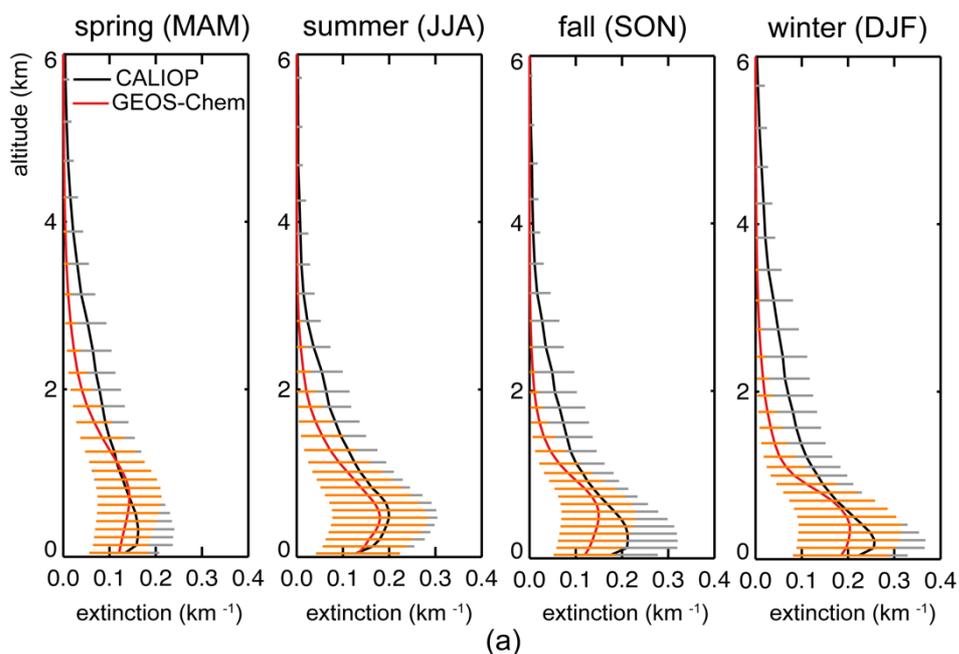

1026 Figure 2. Seasonal spatial patterns of ALH climatology at 532 nm on a 0.667° long. x
 1027 0.50° lat. grid based on (a) our compiled all-sky Level-2 CALIOP data, (b)
 1028 corresponding GEOS-Chem simulations, and (c) NASA all-sky monthly Level-3
 1029 CALIOP dataset.

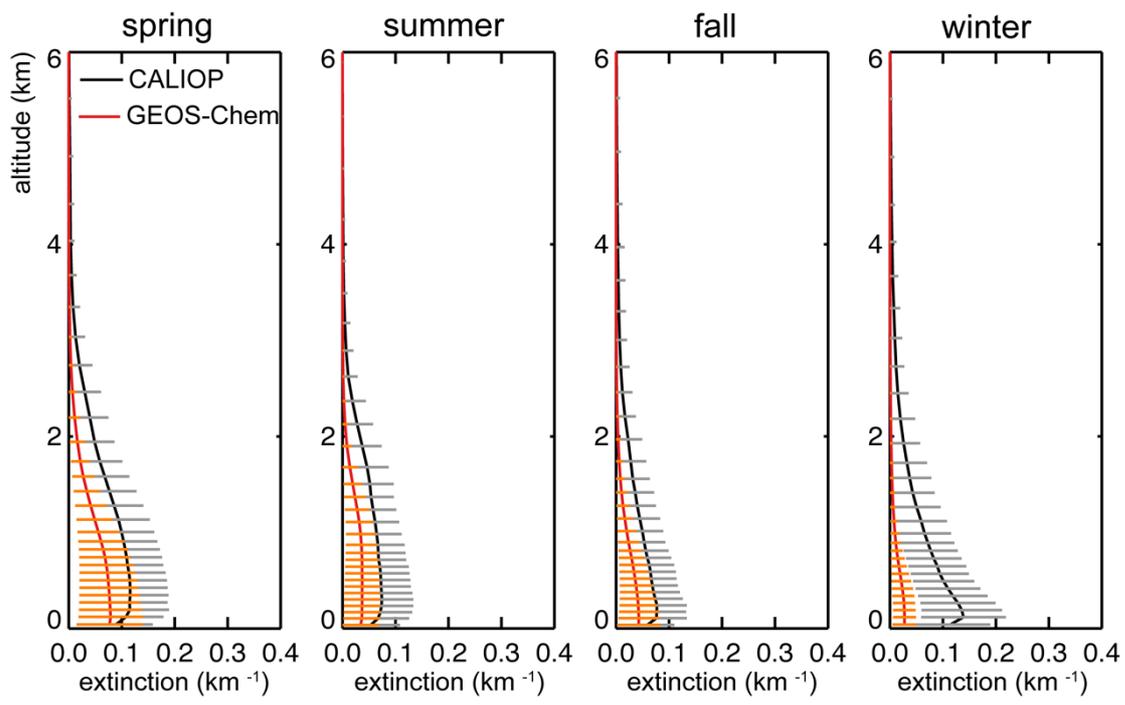

1030 Figure 3. Regional mean ALH monthly climatology over (a) Northern East China, (b)
 1031 Northwest China, and (c) East China. The error bars stand for 1 standard deviation for
 1032 spatial variability.

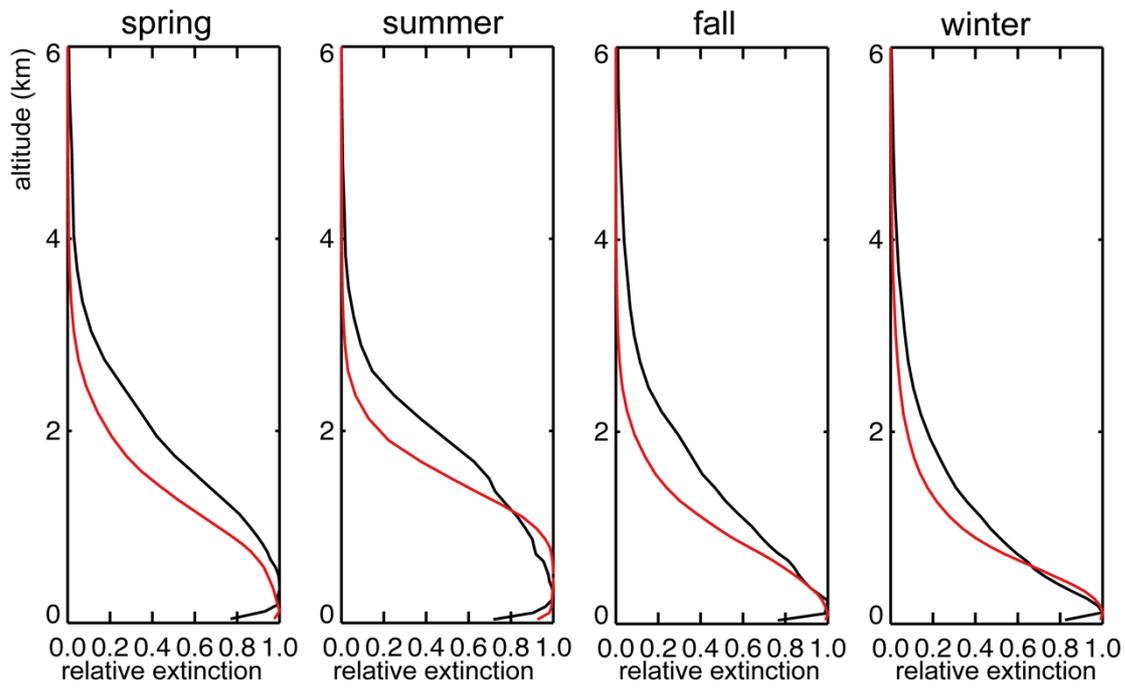

1033

1034 Figure 4. Seasonal climatological aerosol extinction profiles (first row) and
 1035 corresponding relative extinction profiles (normalized to maximum extinction values,
 1036 second row) in spring (MAM), summer (JJA), fall (SON) and winter (DJF) over
 1037 Northern East China. Model results (in red) are prior to MODIS/Aqua based AOD
 1038 adjustment. Error bars in (a) represent 1 standard deviation across all grid cells in each
 1039 season.

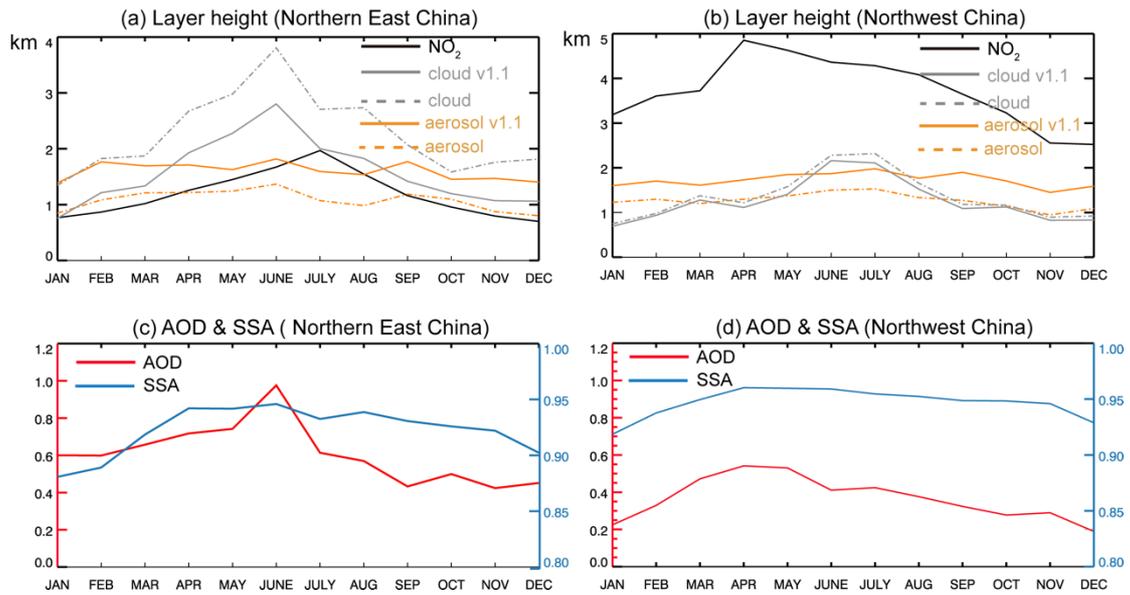

(a)

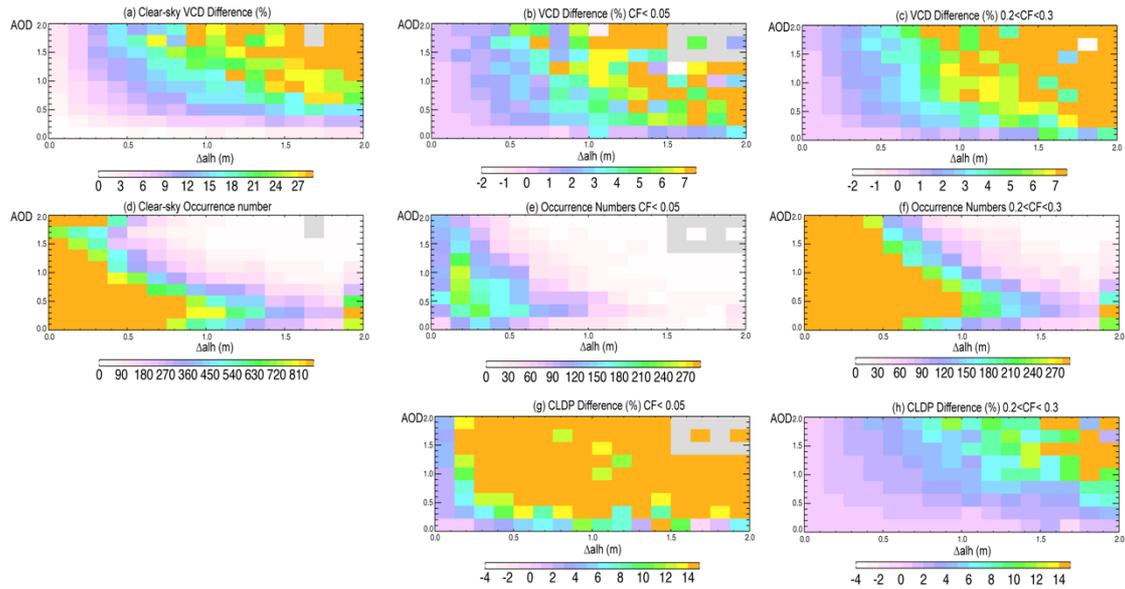

(b)

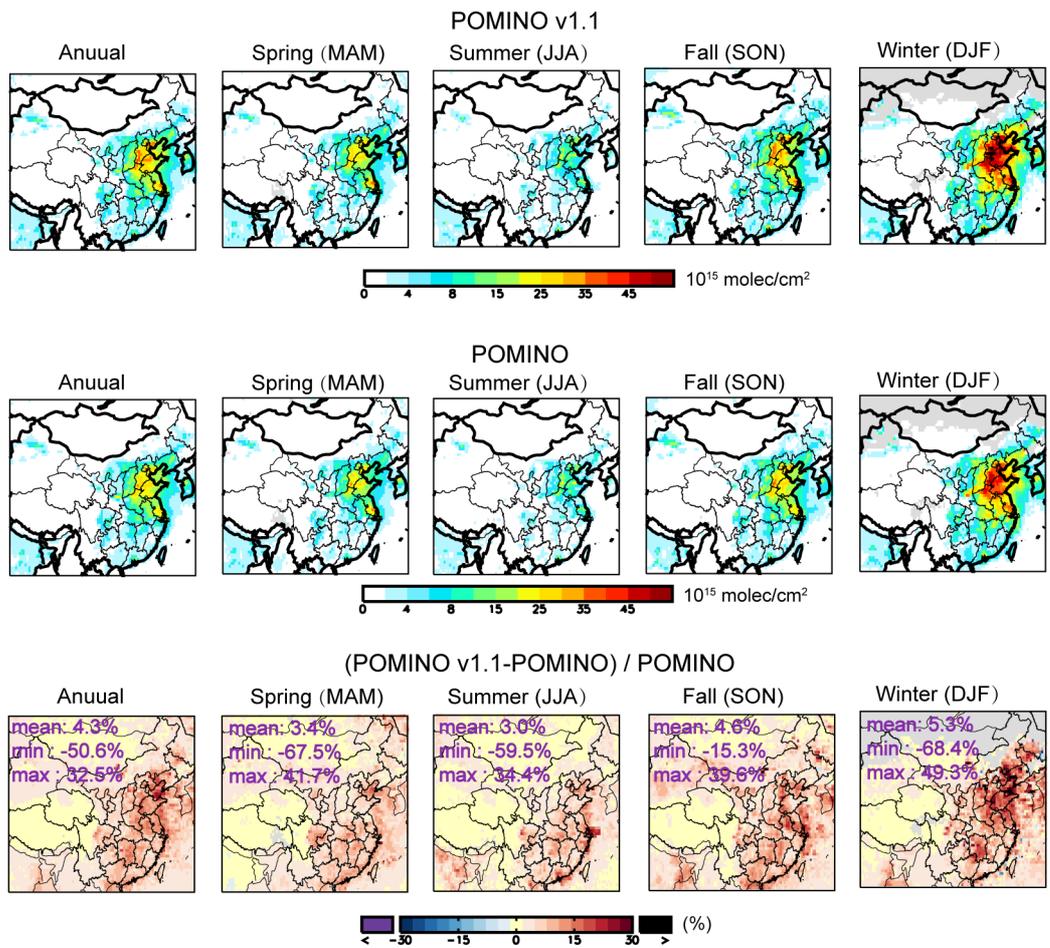

1040 Figure 5. Similar to Fig. 5 but for Northwest China.

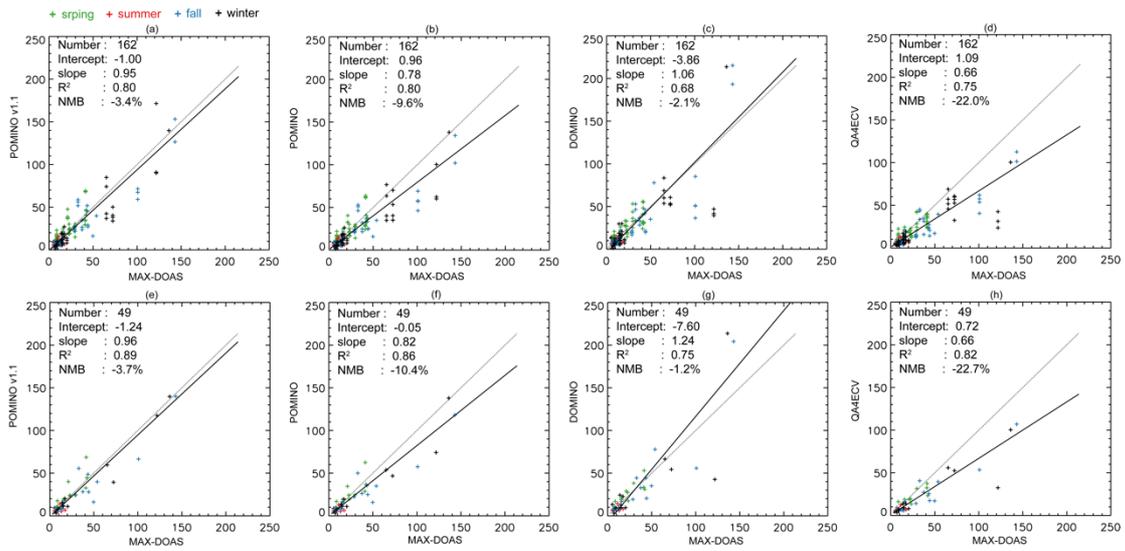

1041 Figure 6. Monthly variations of ALH, CTH and NLH over (a) Northern East China and
 1042 (b) Northwest China in 2012. Data are averaged across all pixels in each month and
 1043 region. The grey and orange solid lines denote POMINO v1.1 results, while the
 1044 corresponding dashed lines denote POMINO. (c–d) Corresponding monthly AOD and
 1045 SSA.

1046 Figure 7. Percentage changes in VCD from POMINO to POMINO v1.1 ($[\text{POMINO}$
 1047 $\text{v1.1} - \text{POMINO}] / \text{POMINO}$) for each bin of ΔALH (bin size = 0.2 km) and AOD (bin
 1048 size = 0.1) across pixels in 2012 over Northern East China, for (a) cloud-free sky (CF
 1049 = 0 in POMINO), (b) little-cloudy sky, and (c) modestly cloudy sky. (d-f) The number
 1050 of occurrences corresponding to (a-c). (g, h) Similar to (b, c) but for the percentage
 1051 changes in cloud top pressure (CP).

1052 Figure 8. Seasonal spatial distribution of tropospheric NO₂ VCD in 2012 for (a)
 1053 POMINO v1.1, (b) POMINO, and (c) their relative difference.

1054 Figure 9. (a–d) Scatterplot for NO₂ VCDs (10¹⁵ molec. cm⁻²) between MAX-DOAS
 1055 and each of the three OMI products. Each “+” corresponds to an OMI pixel, as several
 1056 pixels may be available in a day. (e–h) Similar to (a–d) but after averaging over all OMI
 1057 pixels in the same day, such that each “+” represents a day. Also shown are the statistic
 1058 results from the RMA regression. The black solid line indicates the regression curve and the grey dotted line depict the 1:1 relationship.

1060

1061
