20 **Abstract**
21 The majority of aerosol data are obtained from daytime measurements, and there are
22 few datasets available for studying nighttime aerosol characteristics. In order to
23 estimate the aerosol optical depth (AOD) and the precipitable water vapor (PWV)
24 during the nighttime using the moon as a light source, a skyradiometer POM-02
25 (Prede Ltd., Japan) was modified. The amplifier was adjusted so that POM-02 could
26 measure lower levels of input irradiance. In order to track the moon based on the
27 calculated values, a simplified formula was incorporated into the firmware. A new
28 position sensor with a four-quadrant detector to adjust the tracking of the sun and
29 moon was also developed.
30   The calibration constant, which is the sensor output for the extra-terrestrial solar
31 and lunar irradiance at the mean earth-sun distance, was determined by using the
32 Langley method. The measurements for the Langley calibration were conducted at
33 the National Oceanic and Atmospheric Administration/Mauna Loa Observatory
34 (NOAA/MLO) from Sep. 28, 2017 to Nov. 7, 2017. By assuming that the correct
35 reflectance is proportional to the reflectance estimated by the Robotic Lunar
36 Observatory (ROLO) irradiance model, the calibration constant for the lunar direct
37 irradiance was successfully determined using the Langley method. The ratio of the

calibration constant for the moon to that for the sun was often greater than 1; the value of the ratio was 0.95 to 1.18 in the visible and near-infrared wavelength region. This indicates that the ROLO model often underestimates the reflectance. In addition, this ratio depended on the phase angle. In this study, this ratio was approximated by a quadratic equation of the phase angle. By using this approximation, the reflectance of the moon can be calculated to within an accuracy of 1% or less.

In order to validate the estimates of the AOD and PWV, continuous measurements with POM-02 were conducted at the Japan Meteorological Agency/Meteorological Research Institute (JMA/MRI) from January 2018 to May 2018, and the AOD and PWV were estimated. The results were compared with the AOD and PWV obtained by independent methods. The AOD was compared with that estimated by the National Institute for Environmental Studies (NIES) High Spectral Resolution Lidar measurements (wavelength: 532 nm), and the PWV was compared with the PWV obtained from a radiosonde and the Global Positioning System. In addition, the continuity of the AOD (PVW) before and after sunrise and sunset in Tsukuba was examined, and the AOD (PWV) of AERONET and that of POM-02 at MLO were compared. In the results, the daytime and nighttime AOD (PWV) measurements are shown to be statistically almost equivalent. The AODs (PWVs) during the daytime and nighttime for POM-02 are presumed to have the same degree of precision and accuracy within the measurement uncertainty.

1. Introduction

Atmospheric aerosols are an important constituent of the atmosphere. Aerosols change the radiation budget directly by absorbing and scattering solar radiation and indirectly through their role as cloud condensation nuclei (CCNs), thereby increasing cloud reflectivity and lifetime (e.g., Ramanathan et al. 2001; Lohmann and Feichter 2005). Aerosols also affect human health as one of the main components of air pollution (Dockery et al. 1993; WHO 2006, 2013).

Atmospheric aerosols have a large variability in time and space. Therefore, measurement networks covering an extensive area on the ground and from space have been developed and established to determine the spatiotemporal distribution of aerosols. Well-known ground-based networks include AERONET (AErosol RObotic NETwork) (Holben et al. 1998), SKYNET (Takamura et al. 2004), and PFR-GAW (Precision Filter Radiometer-Global Atmosphere Watch) (Wehrli 2005). These observation networks use passive radiometers which measure sunlight in the region

75 from the ultraviolet to shortwave infrared wavelengths and the column average
76 effective aerosol characteristics such as aerosol optical depth (AOD) are retrieved.

77 Using lidar, which is an active remote sensing instrument, several networks have
78 also been constructed: for example, the Micropulse Lidar Network (MPLNET) by
79 NASA (National Aeronautics and Space Administration) (Welton et al. 2001; Levis et
80 al. 2016), the European Aerosol Research Lidar Network (EARLINET) (Pappalardo
81 et al. 2016) in Europe, the Asian Dust and aerosol lidar observation network
82 (AD-Net) (Shimizu et al. 2017) in East Asia, and the Latin American Lidar Network
83 (LALINET) (Guerrero-Rascado et al. 2016) in South America.

84 Several satellite programs provide aerosol optical depth data on a global scale: for
85 example, the Moderate Resolution Imaging Spectroradiometer (MODIS) (Remer et al.
86 2005), Multiangle Imaging Spectroradiometer (MISR) (Kahn et al. 2005),
87 Geostationary Operational Environmental Satellite (GOES) Aerosol Smoke Product
88 (Prados et al. 2007), Sea-viewing Wide Field-of-view Sensor (SeaWiFS) (Wang et al.
89 2000), Advanced Himawari Imager (AHI) (Yoshida et al. 2018; Kikuchi et al. 2018),
90 and Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO)
91 (Winker et al. 2007).

92 With the exception of active sensor measurements such as lidar systems, to
93 estimate aerosol characteristics, direct solar irradiance and scattered solar radiance
94 measured with a passive sensor are required. Therefore, the majority of aerosol
95 property data are obtained by daytime measurements, and there are few datasets of
96 nighttime aerosol characteristics available.

97 To advance the understanding of the diurnal behavior of aerosols, and nocturnal
98 mixing layer dynamics, nighttime continuous AOD measurements are necessary. In
99 particular, in high latitude regions during the winter polar night, aerosol properties
100 cannot be measured using sunlight, and this results in gaps in the long-term aerosol
101 data. Such nocturnal aerosol data would also contribute to the understanding of
102 aerosol transport to polar regions, the influence of aerosol on cloud formation, and
103 the cloud effect on the radiation budget.

104 Lidar instruments can be used to obtain aerosol data during the night. However, in
105 many cases, lidar data retrieval requires some physical or mathematical constraints
106 in inversion algorithms to allow the quantitative interpretation of the lidar
107 backscatter signal (Fernald 1984; Klett 1985). In order to improve the accuracy of the
108 analysis, constraining of the AOD is necessary.

109 In order to measure the optical depth of aerosol at night, research has been
110 conducted using the moon and stars as light sources (Herber et al. 2002; Esposito et
111 al. 1998; Esposito et al. 2003; Pérez-Ramírez et al. 2008). Since the reflectivity of the

moon changes depending on the observation angle, the determination of the calibration coefficient is an important obstacle to overcome (Herber et al. 2002). Instruments for observing stars are large, expensive, and complicated to use due to the low level of incoming energy from stars. Therefore, stellar measurements are limited in use, and no large-scale observation network has been established.

The moon is a bright light source at night and the reflectance properties of the moon's surface are virtually invariant ($<10^{-8}$ yr^{-1}; Kieffer 1997). However, since the surface of the moon is not spatially uniform and has non-Lambertian reflectance, the brightness of the moon as seen by an observer on the earth varies depending on the relationship between the moon, the sun, and the observer, that is, the phase and the lunar libration. Therefore, it is difficult to use the moon as a light source.

However, starting from the 2000s, the quality of reflectance data for the moon has improved. The empirical model known as ROLO (Robotic Lunar Observatory) was developed by the United States Geological Survey (USGS) (Kieffer and Stone 2005). ROLO is a NASA-funded program aimed at using the moon for on-orbit calibration of Earth Observing System (EOS) satellite instruments. Furthermore, the Spectral Profiler (SP) onboard the Japanese Selenological and Engineering Explorer (SELENE, nicknamed Kaguya) measures lunar photometric properties in the region of visible, near-infrared, and shortwave infrared wavelengths (Yokota et al. 2011). These data made it possible to estimate the reflectance of the moon, and thus the moon can be used as a light source for aerosol optical depth estimation.

The Cimel sun photometer used in AERONET has been modified for lunar observation and the aerosol optical depth at night can be estimated (Berkoff et al. 2011; Barreto et al. 2013, 2016, 2017). In addition, a lunar photometer—the Moon Precision Filter Radiometer, LunarPFR (Kouremeti et al. 2016)—has been developed by the Physical Meteorological Observatory in Davos (PMOD), which serves as the World Radiation Center (WRC), based on the sun-PFR experience. Using these instruments and stellar photometers, a multi-instrument nocturnal intercomparison campaign was conducted to evaluate nighttime aerosol measurements and lunar irradiance models (Barreto et al. 2019).

In SKYNET, the radiometers POM-01 and POM-02, manufactured by Prede Co. Ltd., Japan, are used. These radiometers are called 'sky radiometers', and measure both the solar direct irradiance and sky-radiances (Takamura et al. 2004). The sky radiometers POM-01 and POM-02 can measure solar direct irradiance and sky-radiances during the daytime and the measured data are used for estimating aerosol characteristics during the daytime (Takamura et al. 2004). In this study, we will aim to measure the optical depth of aerosol using the moon as a light source by

149　modifying POM-02.

150　　In section 2, we describe our modification of the instrument. In section 3, the
151　ROLO model is briefly explained. In section 4, we briefly describe the data used in
152　this study. In section 5, the calibration method and corresponding results are
153　described. In section 6, we show the results of comparing the aerosol optical depth
154　and precipitable water vapor obtained by continuous observation with those obtained
155　by other independent instruments. We also show the results of comparing the aerosol
156　optical depth and precipitable water vapor before and after sunrise and sunset using
157　the continuous observation data. Furthermore, we show the results of a comparison
158　between the AERONET and POM-02 data during the period of the MLO calibration
159　measurement.

160

161　2.　Modification of instrument

162

163　　In the modification of the POM-02 for solar observation, only the amplifier and the
164　position sensor were changed. The other components, e.g., detectors, filters, and
165　lenses, are not changed. Therefore, the magnitude of the solid view angle (field of
166　view) for the new POM-02 is the same as in the non-modified POM-02.
167　Measurements can still be obtained in the daytime using the modified POM-02.

168

169　2.1 Adjustment of Amplifier

170

171　　The sky radiometer POM-02 is designed to measure the direct solar irradiance and
172　the scattered sky radiance with a single radiometer. An example of the calibration
173　constant, which is the sensor output for the extra-terrestrial solar irradiance at the
174　mean earth-sun distance (1 astronomical unit (AU)) at the reference temperature, is
175　shown in Table 1. The calibration constant is $1.8{\times}10^{-5}$ to $3.4{\times}10^{-4}$ A in the visible and
176　near-infrared region, and $7.9{\times}10^{-5}$ to $1.3{\times}10^{-4}$ A in the short-wavelength infrared
177　region. Figure 1 shows an example of measurements of scattered radiances in the
178　visible and near-infrared wavelength region. The output for the scattered radiance
179　from the sky is $1{\times}10^{-7}$ to $1{\times}10^{-10}$ A, and this value is $1{\times}10^{-6}$ smaller than the output
180　for the direct solar irradiance. The direct lunar irradiance is $1{\times}10^{-5}$ as strong as the
181　direct solar irradiance during a full moon, and $1{\times}10^{-6}$ during a half-moon (Berkoff et
182　al. 2011). From Table 1, the calibration constants at 340 and 380 nm are $1.8{\times}10^{-5}$ and
183　$1.9{\times}10^{-5}$ (about $2{\times}10^{-5}$), respectively. Therefore, the output for the direct lunar
184　irradiance during the half moon is about $2{\times}10^{-5} \times 10^{-6} = 2{\times}10^{-11}$ in the 340 and 380
185　nm channels. This is close to the detectable limits of the current POM-02. Without

186 modification, it is possible to measure the direct lunar irradiance with the current
187 POM-02 except for wavelengths between 340 and 380 nm where the sensitivity of the
188 detector is low and wavelengths of 1225, 1627, and 2200 nm with poor S/N.

189 Table 2 shows the measurement ranges before and after modification of POM-02.
190 POM-02 measures input energy in seven ranges according to the magnitude of the
191 input energy, and the measured value is digitized with 15 bits. After modification the
192 measurement ranges are slightly expanded, and the measurement limit depends on
193 the magnitude of the dark current and the magnitude of the noise. The sensor output
194 takes into account the magnification of the amplifier, and the same amplifier was
195 used for both the solar and lunar measurements.

196 The dark current of the detector in the visible and near-infrared region was about
197 5×10^{-13} A, and the RMS of the random component of the noise was 4×10^{-14} A. In
198 consideration of these values, the new POM-02 can use amplifiers for measurement
199 ranges 1 to 7 and the minimum meaningful current is about 4×10^{-13} A (~RMS×10) in
200 the visible and near-infrared region. This value is smaller than the output for the
201 direct solar irradiance by a factor of 1×10^{-8} to 1×10^{-9}.

202 The dark current of the detector in the shortwave infrared wavelength region was
203 about 1.5×10^{-8} A, and the RMS of the random component of the noise was 4×10^{-11} A.
204 The measurement range is limited due to the large dark current. The new POM-02
205 can use amplifiers for measurement ranges 1 to 5 and the minimum meaningful
206 current is about 4×10^{-10} A (~RMS×10). This value and the magnitude of the
207 measured value of the direct lunar irradiance are comparable. Therefore, it is
208 difficult to measure the direct lunar irradiance even with the new POM-02 in the
209 shortwave infrared wavelength region.

210

211 2.2 Sun and moon position sensor

212

213 The tracking of the sun and the moon is based on the calculated position. The moon
214 positions are calculated with the simplified formula in Nagasawa (1981). The
215 necessary software is installed in the firmware of POM-02. Deviations may occur
216 even if the instrument is pointed in the calculated direction due to errors in the moon
217 position calculation, instrument installation errors, misalignment of the rotation
218 axis, and so on. A position sensor is used to correct this deviation.

219 A position sensor with a four-quadrant detector is used to adjust the tracking of the
220 sun and the moon. In order to adjust the tracking of the moon, a position sensor
221 incorporating a new electronic circuit to amplify the signal and new software to
222 process the signal data were developed. The new position sensor can be used to track

6

223 both the sun and the moon.

224 When the input energy to the position sensor is small, it is difficult to adjust the
225 tracking with the position sensor. The magnitude of the input energy to the position
226 sensor varies depending on the lunar phase and the aerosol optical depth. It was
227 confirmed that the function of the moon tracking adjustment works during the
228 period of the full moon ± about 90 degrees of the phase angle (half-moon).

229 Whether the position sensor can be used can be determined by a user-specified
230 threshold value. That is, the position sensor can be deactivated when the input
231 energy to the position sensor becomes less than the threshold value. For phase
232 angles larger than the half-moon, the signal of the position sensor was small, and the
233 position sensor was deactivated.

234 When the position sensor is not functioning, tracking is performed based on the
235 calculated values. When comparing the moon position calculated by this simplified
236 formula with that calculated using the NASA SPICE toolkit (Acton 1996), the
237 difference in the zenith angle is less than 0.01 degrees, and the difference in the
238 azimuth angle is less than 0.04 degrees. The center of the field of view has a flat
239 region of ±0.5 degrees; the flat region is ±0.25 degrees in the solar disk scan. The
240 apparent diameters of the sun and the moon are about 0.5 degrees. Since the
241 calculation error of the moon position is less than 0.25 degrees, if the misalignment
242 of the rotation axis is negligible and POM-02 is installed correctly, it is possible to
243 track the moon using only the calculated positions. In fact, measurements could be
244 made on the day of a full moon ± 10 days (phase angle about 120 degrees). Figure 2
245 shows an example of the measurements on Oct. 14, 2017 at NOAA/MLO. In this
246 example, the phase angle of the moon is from 117.6 to 118.0 degrees.

247

248 3. Robotic Lunar Observatory (ROLO) irradiance model

249

250 In order to estimate the aerosol optical thickness using the moon as a light source,
251 measurement of the extra-terrestrial irradiance of the moon is necessary. In this
252 study, a model known as the ROLO irradiance model (Kieffer and Stone 2005) was
253 used. This model was developed at the U.S. Geological Survey (USGS) and is based
254 on an extensive database of radiance images acquired by the ground-based ROLO
255 over more than 8 years. ROLO is a NASA-funded program designed to use the moon
256 for on-orbit calibration of Earth Observing System (EOS) satellite instruments. The
257 empirical irradiance model was developed for 32 wavelengths from 350 to 2450 nm
258 and has the same form for each wavelength. The average residual is less than 1%.
259 The coefficients of the empirical formula were constrained and determined using

data with a phase angle between 1.55 and 97 degrees. The empirically derived analytic form based on the primary geometric variables is as follows:

$$\ln A_k = \sum_{i=0}^{3} a_{ik} g^i + \sum_{j=1}^{3} b_{jk} \Phi^{2j-1} + c_1\phi + c_2\theta + c_3\Phi\phi + c_4\Phi\theta$$
$$+ d_{1k} e^{-g/p_1} + d_{2k} e^{-g/p_2} + d_{3k} \cos((g-p_3)/p_4) \tag{1}$$

where A_k is the disk-equivalent reflectance, g is the absolute phase angle in radians, θ and ϕ are the selenographic latitude and longitude of the observer in degrees, and Φ is the selenographic longitude of the sun in radians.

This formula must be used with caution. The equation in Kieffer and Stone (2005) has well-known typographical errors. In eq. (1), θ and ϕ in the original expression by Kieffer and Stone (2005) are exchanged. In addition, the units of the coefficients p_1, p_2, p_3, and p_4 are degrees. Therefore, in order to make the dimensions the same, g in the exponent and the cosine terms must be converted into units of degrees.

The astronomical parameter was calculated using our own software developed using the NASA SPICE toolkit; an observation geometry information system named SPICE is offered by NASA's Navigation and Ancillary Information Facility (NAIF) (Acton, 1996). SPICE is widely used in the NASA and international planetary exploration communities (for more information about SPICE, refer to the NAIF webpage at http://naif.jpl.nasa.gov.).

In this study, only the values of the reflectance are used, and it is assumed that there is an error in the ROLO reflectance and that the correct reflectance is proportional to the ROLO reflectance. This indicates that the relative variation in the ROLO reflectance is assumed to be correct. The reflectance values are not converted to irradiance values by assuming the extra-terrestrial solar spectral irradiance. The wavelength of POM-02 used in this study does not necessarily match the wavelength of the ROLO model. Here, the reflectance at the wavelength of POM-02 was calculated by linearly interpolating from the reflectance of the ROLO model at two adjacent wavelengths. Information on the filters used in the ROLO measurement was not available. Here, the wavelength is represented by the center wavelength. In addition, the ROLO model does not have reflectance data for the wavelength 340 nm. The reflectance at the wavelength 340 nm was obtained by extrapolating linearly from the values at the two end wavelengths.

4. Data

4.1 Data for Langley calibration

294

The aerosol optical thickness is estimated by measuring the attenuation of the direct solar or lunar irradiance. Therefore, in order to estimate the aerosol optical thickness, the output of the instrument for the input irradiance at the top of the atmosphere is necessary. The determination of this constant is referred to as calibration, and the output of the instrument for the extra-terrestrial solar or lunar irradiance at the mean earth-sun distance (1 AU) at the reference temperature is called the calibration constant. In this study, the calibration constant was determined by the Langley method.

To calibrate the POM-02 by the Langley method, measurements were conducted at the NOAA Mauna Loa Observatory (MLO) during the period from Sep. 28, 2017 to Nov. 7, 2017; the full moon was on Oct. 4 and Nov. 3, 2017. The MLO (19.5362°N, 155.5763°W) is located at an elevation of 3397.0 meters amsl on the northern slope of Mauna Loa, Island of Hawaii, Hawaii, USA. The atmospheric pressure is about 680 hPa. The MLO is one of the most suitable places to obtain data for a Langley plot for the solar direct irradiance measurement (Shaw 1983). Though the air at MLO is highly transparent, it is affected in the late morning and afternoon hours by marine aerosol that reaches the observatory during the marine inversion boundary layer breakdown under solar heating (Shaw 1983; Perry et al. 1999). Therefore, using data taken in the morning is recommended (Shaw 1982; Dutton et al. 1994; Holben et al. 1998).

However, during the nighttime, the upslope winds change to downslope winds, which bring low moisture and aerosol-poor air above the marine boundary layer down to the observatory. As a result, daytime orographic clouds at the observatory disappear and the atmosphere stratification becomes stable. These atmospheric conditions are suitable for obtaining data for the Langley plot from the lunar direct irradiance measurement.

During the calibration period, the data obtained for the moon over 18 nights for the visible and near-infrared region, and 13 nights for the short wavelength infrared region and water vapor channel (940 nm) were used to determine the calibration constants. The data obtained for the sun over 22 days for the visible, near-infrared, and short wavelength infrared region, and 24 days for the water vapor channel (940 nm) were used to determine the calibration constants.

4.2 Continuous measurement for comparison

The measurements for the estimation of the aerosol optical depth and precipitable

9

water vapor were performed at 1-minute intervals at the Japan Meteorological Agency/Meteorological Research Institute (JMA/MRI) (36.05°N, 140.13°E) in Tsukuba, which is located about 50 km northeast of Tokyo. The comparison was made using data obtained during the period from Jan. 1 to May 31, 2018. During this period, the AOD and the precipitable water vapor (PWV) were estimated assuming the calibration constant was unchanged.

The optical depth estimated from POM-02 was compared with the value of the National Institute for Environmental Studies (NIES) High Spectral Resolution Lidar (HSRL, wavelength; 532 nm). The NIES/HSRL is one of the lidar operated by the lidar measurement group of the NIES (Shimizu et al. 2016). The NIES and MRI observation sites are located about 800 m apart. Since the POM-02 was not measured at the 532 nm wavelength, the AOD at 532 nm was interpolated from the values of 500 nm and 675 nm by assuming that AOD is proportional to $\lambda^{-\alpha}$, where λ is the wavelength. Furthermore, since the AOD of NIES/HSRL is the 15-minute average, the value of POM-02 was also averaged over 15 minutes.

The PWV estimated from POM-02 was compared with that obtained from the vertical profile of a radiosonde and that obtained from the Global Positioning System (GPS) receiver. The radiosonde observation is operated from the JMA Aerological Observatory, which is adjacent to JMA/MRI. The GPS receiver is installed at JMA/MRI, and GPS data were processed by one of the JMA/MRI researchers (Shoji et al. 2013). The comparison of the PWV was performed using the 30-minute average values.

5. Calibration of POM-02 using MLO data

5.1 Langley method

In this study, the calibration constant was determined by the Langley method (Uchiyama et al. 2018). Here, we do not consider the temperature dependence of the sensor output for the POM-02. Under these observation conditions in Tsukuba, the temperature dependence of the sensor output can be ignored except for the 340, 380, and 2200 nm channels (Uchiyama et al. 2018).

The sensor output when measuring the direct solar irradiance can be written as follows:

$$V(\lambda_0) = \frac{V_{S0}(\lambda_0)}{R_S^{\,2}} \exp(-m(\theta)\tau(\lambda_0))\overline{T}_{gas}(\lambda_0, \theta) \tag{2}$$

where $V(\lambda_0)$ is the sensor output in the λ_0 wavelength channel, R_S is the earth-sun distance in AU, $m(\theta)$ is the total airmass, $\tau(\lambda)$ is the total optical

367   depth, θ is the solar zenith angle, and $\bar{T}_{gas}(\lambda_0, \theta)$ is the channel average

368   transmittance of the gas line absorption. Furthermore, $V_{S0}(\lambda_0)$ is the sensor output

369   for the extra-terrestrial solar irradiance at 1 AU, and is called the calibration

370   constant. $\tau(\lambda)$ consists of the optical thickness for molecular scattering (Rayleigh

371   scattering), aerosol, and the continuous absorption of gas. In this study, it is assumed

372   that airmass $m(\theta)$ is the same for all components. The airmass $m(\theta)$ for

373   molecular scattering is used (Schmid and Wehrli 1995; Holben et al. 1998).

374   In the case of no "gas absorption", the following equation is used:

375
$$V(\lambda_0) = \frac{V_{S0}(\lambda_0)}{R_S^{\ 2}} \exp(-m(\theta)\tau(\lambda_0)) \tag{3}$$

376   Taking the logarithm of the equation leads to

377
$$\begin{aligned}
\ln(V(\lambda_0)R_S^{\ 2}) &= \ln V_{S0}(\lambda_0) - m(\theta)\tau(\lambda_0) \\
&= C_1 m(\theta) + C_2
\end{aligned} \tag{4}$$

378   The parameters on the left-hand side are known: V is the measurement value, and

379   R_S and $m(\theta)$ can be calculated from the solar zenith angle. For example, R_S can

380   be calculated with the simplified formula in Nagasawa (1981), and $m(\theta)$ can be

381   calculated as in Kasten and Young (1989). In the case of POM-02, the sensor output

382   is the current, and the unit of the measurements of V is the ampere A. $C_2 = \ln V_{S0}$

383   is determined from the ordinate intercept of a least-square fit when one plots the

384   left-hand side of the above equation versus airmass $m(\theta)$.

385   For the water vapor absorption band at a wavelength of 940 nm, the

386   Beer-Lambert-Bouguer law is not valid. Calibration methods for the 940 nm channel,

387   which is in the water vapor absorption band, have been considered extensively in

388   previous studies (Reagan et al. 1987a, 1987b, 1995; Bruegge et al. 1992; Thome et al.

389   1992, 1994; Michalsky et al. 1995, 2001; Schmid et al. 1996, 2001; Shiobara et al.

390   1996; Halthore et al. 1997; Cachorro et al. 1998; Plana-Fattori et al. 1998, 2004;

391   Ingold et al. 2000; Kiedron et al. 2001, 2003; Uchiyama et al. 2014, Campanelli et al.

392   2014).

393   In this study, the modified Langley method is used (Reagan et al. 1987a; Bruegge

394   et al. 1992; Schmid and Wehrli 1995). In the modified Langley method, the

395   transmittance is approximated by an empirical formula. The water vapor

396   transmittance is approximated as follows:

397
$$Tr(\mathrm{H2O}) = \exp(-a(m(\theta) \cdot pwv)^b) \tag{5}$$

398   where a and b are fitting coefficients, and pwv is PWV.

399   Coefficients a and b were determined by computing the transmittance for several

400   atmospheric models (Uchiyama et al. 2014).

401   The output of the 940 nm channel can be written as follows:

402
$$V(\lambda_0) = \frac{V_{S0}(\lambda_0)}{R_S^2} \exp(-m(\theta)\tau(\lambda_0))Tr(H2O)$$
$$= \frac{V_{S0}(\lambda_0)}{R_S^2} \exp(-m(\theta)\tau(\lambda_0))\exp(-a(m(\theta)\cdot pwv)^b)$$
(6)

403   Taking the logarithm of the equation leads to

404
$$\ln VR_s^2 + m(\theta)(\tau_{aer} + \tau_R) = \ln V_{S0} - a(pwv)^b m(\theta)^b$$
$$= C_1' m(\theta)^b + C_2'$$
(7)

405   In the same way as the normal Langley method, the parameters on the left-hand side
406   are known: V is the measurement value, and R and $m(\theta)$ can be calculated from
407   the solar zenith angle. τ_R is also estimated from the surface pressure; for example,
408   τ_R can be calculated as in Asano et al. (1983). In addition, τ_{aer} is the aerosol optical
409   depth at the 940 nm wavelength, which is interpolated from the aerosol optical depth
410   from the values at the 870 and 1020 nm wavelengths.

411   If pwv is constant, then the right-hand side of the equation is a linear function of
412   $m(\theta)^b$. Therefore, the values on the left-hand side can be fitted by a linear function
413   of $m(\theta)^b$, and the intersection of the y-axis and the fitted line is $\ln V_{S0}$.

414

415   5.2 Langley method for the moon

416

417   The sensor output when measuring the direct lunar irradiance can be written as
418   follows:

419
$$V(\lambda_0) = \frac{\tilde{A}_{ROLO}}{\pi} \Omega_M \frac{V_{S0}(\lambda_0)}{R_S^2} \cdot \frac{1}{R_m^2} \exp(-m(\theta)\tau(\lambda_0))\bar{T}_{gas}(\lambda_0,\theta)$$
(8)

420   where Ω_M is the solid angle of the moon, R_S is the distance between the moon
421   and the sun in AU, and R_m is the distance between the moon and the observer
422   normalized by 384,400 km (the mean radius of the moon's orbit around the earth).

423   $\tilde{A}_{ROLO}$ is the smoothed ROLO reflectance adjusted to the laboratory reflectance

424   spectra of the Apollo 16 samples. $\tilde{A}_{ROLO}$ is calculated using the lunar reflectance

425   A_{ROLO} with the ROLO irradiance model by the method shown in Kieffer and Stone

12

426   (2005) (see Appendix A).

427   Let $\tilde{A}_{ROLO} = F_C A_{ROLO}$, where F_C is a constant for smoothing (see Appendix A).

428   Using this equation, eq. (8) becomes

429
$$V(\lambda_0) = \frac{F_C A_{ROLO}}{\pi} \Omega_M \frac{V_{S0}(\lambda_0)}{R_S^{\,2}} \cdot \frac{1}{R_m^{\,2}} \exp(-m(\theta)\tau(\lambda_0))\bar{T}_{gas}(\lambda_0,\theta) \qquad (9)$$

430   It is known that the aerosol optical depth retrieved using the ROLO reflectance

431   contains an error, which is dependent on the phase angle (Barreto et al. 2016, 2017,

432   2019, JurySek and Prouza 2017). We assume that there is an error in the ROLO

433   reflectance and that the correct lunar reflectance is proportional to the ROLO

434   reflectance. This indicates that the relative variation in the ROLO model reflectance

435   is assumed to be correct. Let the proportional constant be denoted C', and A_{ROLO}

436   in eq. (9) be replaced with $C' \cdot A_{ROLO}$. Equation (9) then becomes

437

438
$$V(\lambda_0) = \frac{F_C C' A_{ROLO}}{\pi} \Omega_M \frac{V_{S0}(\lambda_0)}{R_S^{\,2}} \cdot \frac{1}{R_m^{\,2}} \exp(-m(\theta)\tau(\lambda_0))\bar{T}_{gas}(\lambda_0,\theta)$$
$$= \frac{C A_{ROLO}}{\pi} \Omega_M \frac{V_{S0}(\lambda_0)}{R_S^{\,2}} \cdot \frac{1}{R_m^{\,2}} \exp(-m(\theta)\tau(\lambda_0))\bar{T}_{gas}(\lambda_0,\theta) \qquad (10)$$

439   where $F_C C'$ is substituted with C.

440   In the case of no "gas absorption", taking the logarithm of the equation leads to

441
$$\ln(\frac{\pi V(\lambda_0)}{A_{ROLO}\Omega_M} R_S^{\,2} R_m^{\,2}) = \ln C V_{S0}(\lambda_0) - m(\theta)\tau(\lambda_0)$$
$$= \ln V_{m0}(\lambda_0) - m(\theta)\tau(\lambda_0) \qquad (11)$$
$$= C_1'' m(\theta) + C_2''$$

442   where $V_{m0}(\lambda_0) = C V_{S0}(\lambda_0)$. $C_2'' = \ln V_{m0}$ is determined from the ordinate intercept

443   of a least-square fit when one plots the left-hand side of the above equation versus

444   airmass $m(\theta)$.

445   V_{S0} can be determined by applying the Langley method to data taken during the

446   daytime. If V_{S0} is determined, the coefficient C can be determined by taking the

447   ratio of V_{m0} and V_{S0}. If the coefficient C is 1, the reflectance of the ROLO model

448   will be correct. If the coefficient C is greater than 1 (less than 1), the reflectance in

449   the ROLO model is under-estimated (over-estimated).

450

451   5.2 Results

452

453   Examples of Langley plots in the visible and near-infrared wavelengths are shown

454   in Fig. 3. In these examples, the regression lines can be well determined for any

455   wavelength. $C_2'' = \ln V_{m0}$ is determined from the ordinate intercept of the regression

456   line (see eq. (11)). At the 340 nm wavelength, the regression line tends to deviate

457   from the measured values in the region of airmasses larger than 6. It is presumed

458   that the detector output at the 340 nm wavelength is small and hence may be

459   nonlinear. The output at the time of observation was about 1×10^{-12} A. When using

460   output values less than this, the user needs to treat their results with caution. At the

461   940 nm wavelength, the modified Langley method was applied. In this example, the

462   regression line provides a good fit.

463   In Fig. 4, examples of the Langley plot in the shortwave infrared region (1225, 1627,

464   2200 nm) are shown. The detector output of these channels range from 2×10^{-10} to

465   5×10^{-10} A, and the root mean square error of the random noise is 4×10^{-11} A. The ratio

466   of noise to detector output is large and it is difficult to use these channels for

467   estimating the aerosol optical depth.

468   In Fig. 5, the relationship between the coefficient $C(= V_{m0} / V_{S0})$ and the phase

469   angle in the visible and near-infrared wavelength region (from 340 to 1020 nm) is

470   shown. As shown in the previous section, the corrected lunar reflectance is assumed

471   to be proportional to the ROLO reflectance, and the proportional coefficient C is the

472   ratio of the calibration constant for the moon and the sun. That is, the coefficient C

473   indicates the error of the ROLO reflectance, and thus more accurate reflectance can

474   be obtained by multiplying the ROLO reflectance by the coefficient C. As can be

475   seen from this figure, the coefficient C is often greater than 1 and depends on the

476   phase angle. At most wavelengths, the coefficient C is small when the absolute

477   value of the phase angle is small (near the full moon) and increases as the absolute

478   value of the phase angle increases. The range of C is 0.95 to 1.18. The absorption

479   band of water vapor is at the 940 nm wavelength. Water vapor in the atmosphere

480   tends to fluctuate. Therefore, it is difficult to make accurate Langley plots, and the

481   accuracy of both V_{S0} and V_{m0} is poor. Therefore, no clear relationship between C

482   and the phase angle is found, but the coefficient C is about 1.16. The fact that C is

483   larger than 1 means that the reflectance of the ROLO irradiance model is

484   underestimated.

485   In Fig. 6, the relationship between the coefficient $C(= V_{m0} / V_{S0})$ and the phase

486   angle in the shortwave infrared wavelength region (1225, 1627, 2200 nm) is shown.

487 In these channels, the error for C is large, but the coefficient C depends on the
488 phase angle as in the visible and near-infrared wavelength region; C is small when
489 the phase angle is near zero and increases as the absolute value of the phase angle
490 increases.

491 In this study, the phase angle dependence of the coefficient C is approximated by
492 a quadratic equation of the absolute value of the phase angle:

493 $C = A_c \cdot g^2 + B_c$ (12)

494 where g is the phase angle.

495 That is,

496 $V_{m0} = V_{S0} \cdot (A_c \cdot g^2 + B_c)$ (13)

497 The coefficients A_c and B_c are shown in Table 3. The regression line was plotted
498 in Figs. 5 and 6. By using this approximation, the reflectance of the ROLO model can
499 be estimated to within 1% in most channels. By using this approximation, the data
500 processing to estimate the aerosol optical depth from the measured value becomes

501 straightforward. The coefficients, F_C, for smoothing the ROLO reflectance are also

502 shown in Table 3. The coefficients A_c' and B_c' of the regression equation when

503 using the smoothed ROLO reflectance are also given.

504 The size of the error in the reflectance in the ROLO irradiance model is dependent
505 on the phase angle. The ROLO reflectance was obtained by dividing the lunar
506 irradiance measured by Kieffer and Stone (2005) by the solar spectral irradiance of
507 the 1985 Wehrli Standard Extraterrestrial Solar Irradiance Spectrum (Wehrli 1985,
508 Neckel and Labs 1981). The solar spectral irradiances are dependent on the solar
509 spectral models. Therefore, the ROLO reflectance includes an error due to the error
510 in the solar spectral irradiance of 1985 Wehrli. Instrument performance, data
511 processing, and so on are also sources of error. In this study, C is approximated as a
512 symmetric quadratic equation of the phase angle, but the phase angle dependence of
513 C is asymmetric (see Figs. 5 and 6). The applicable range of the ROLO reflectance
514 model is a phase angle of about 95 degrees or less. In order to improve the accuracy of
515 the ROLO reflectance model and expand its application range, it is necessary to
516 further accumulate the reflectance data of the moon.

517

518 6. Results of comparison

519

520 In order to validate the estimations of AOD and PWV, we compared them with the
521 AOD and PWV obtained by independent methods. We investigated whether there is

15

522   a difference between daytime and nighttime measurements, and compared the
523   measurements for the daytime and nighttime with measurement data which was
524   recorded independently of POM-02 and has the same accuracy and precision in the
525   daytime and nighttime.
526   Furthermore, the continuity of the AOD and PWV before and after sunrise and
527   sunset was investigated, and the AOD and PWV of AERONET and POM-02 at MLO
528   were also compared.
529
530   6.1 Aerosol optical depth (AOD)
531
532   The AOD estimated from POM-02 was compared with the value of the NIES/HSRL
533   (wavelength: 532 nm).
534   Figures 7 (a) and (b) show the scatter plot of the aerosol optical depth during the
535   daytime and nighttime, respectively. In Fig. 7 (c), the scatter plot during the
536   nighttime is shown together with that during the daytime. Table 4 shows the results
537   of the comparison between NIES/HSRL and POM-02 AOD: the statistics of the
538   difference between the two AODs, the coefficients of the linear regression equation of
539   NIES/HSRL and POM-02 AOD ($\tau_{HSRL} = C_1 \cdot \tau_{POM\,02} + C_2$), the RMSE of the residual,
540   the 95% confidence interval of the coefficients, and the number of observations.
541   The difference in the slope value of the regression coefficients is 0.1600 (= 1.0477 −
542   0.8877). The 95% confidence interval of the coefficient is about ±0.04 during both the
543   daytime and the nighttime. It cannot be said that the slopes of the two regression
544   lines are equal based on their 95% confidence intervals. However, the correlation
545   between NIES/HSRL and POM-02 AOD is high, and the differences between them
546   and their RMSEs are similar. Furthermore, as shown in Fig. 7 (c), the scatter
547   diagrams for the daytime and nighttime are almost overlapping, and it seems that
548   the two sets of measurements obtained similar results.
549   Examples of time series of the AOD from NIES/HSRL and POM-02 are shown in
550   Fig. 8. As can be seen from these figures, the AOD of the daytime and nighttime
551   estimated from POM-02 constitute a continuous series. The AOD from NIES/HSRL
552   and that from POM-02 have qualitatively similar time variations. However, in these
553   limited examples, while there are periods when the values are consistent, there are
554   periods when there are systematic differences.
555   In the NIES/HSRL data processing, the AOD below an altitude of 500 m is
556   calculated by using the value of the extinction coefficient for an altitude of 500 m.
557   Since the height of the atmospheric boundary layer is typically 1500 to 2000 m, a
558   large amount of aerosols exist at altitudes below 500 m. If the actual distribution

16

559   deviates from the assumed distribution, the estimated AOD is shifted systematically.

560   In Fig. 8 only limited examples were shown, but in the Supplement, the time series

561   of the AOD at 500 nm at Tsukuba for 5 months is shown in Fig. S1. In addition, the

562   time series of the comparison between the HSRL and POM-02 AOD for 5 months is

563   shown in Fig. S3.

564

565   6.2 Precipitable water vapor (PWV)

566

567   The PWV estimated from POM-02 was compared with that obtained from the

568   vertical profile of the radiosonde and that obtained from the GPS receiver. The PWV

569   estimated from the radiosonde data has a frequency of two values per day, whereas

570   the PWV obtained from GPS is continuous.

571

572   6.2.1 Radiosonde

573

574   The PWV from a radiosonde is often used as a reference for the PWV measurement

575   value. The PWV from the radiosonde and PWV from POM-02 are first compared.

576   Figure 9 shows a scatter plot of the PWV from the radiosonde and from POM-02. The

577   red symbol denotes 00 UTC (09 LST), and the blue symbol is 12 UTC (21 LST). Table

578   5 shows the results of the comparison between the radiosonde and POM-02

579   precipitable water vapor (Table 5 is the same as Table 4 except for radiosonde and

580   POM-02 precipitable water vapor).

581   The ratio of PWV estimated from POM-02 and the radiosonde in both daytime and

582   nighttime is almost constant: the slope of the regression line is 0.80 in the daytime

583   and 0.78 in the nighttime.

584   The empirical formula of the transmittance is expressed as eq. (5). The ratio of the

585   two PWVs is almost constant. In addition, as shown in Fig. 5, the modified Langley

586   plot provides a good fit for the data. From these facts, it seems that the value of the

587   coefficient b in eq. (5) is appropriate but the value of the coefficient a in eq. (5)

588   was inappropriate. It is possible that the filter characteristics of the 940 nm channel

589   have changed from the nominal characteristics due to degradation.

590   Let $pwv = c \cdot pwv'$ and rewrite eq. (5) as follows:

591
$$
\begin{aligned}
Tr(\mathrm{H2O}) &= \exp(-a(m(\theta) \cdot (c \cdot pwv'))^b) \\
&= \exp(-ac^b(m(\theta) \cdot pwv')^b)
\end{aligned}
\tag{14}
$$

592   Then the PWV can be corrected by replacing a with ac^b.

593   Figure 10 shows a scatter plot of the PWV from the radiosonde and the corrected

17

594   PWV from POM-02. For the correction coefficient c, the average value of the

595   coefficients C_1 of the daytime and nighttime regression equations was used. Table 6

596   shows the results of the comparison between the radiosonde and corrected POM-02

597   precipitable water vapor (Table 6 is the same as Table 4 except for radiosonde and

598   corrected POM-02 precipitable water vapor).

599   The slope C_1 of the regression line during the daytime and nighttime is 1.0160

600   and 0.9869, respectively, and the difference between them is 0.0291 (= 1.0160 −

601   0.9869). The 95% confidence intervals of the slopes during the daytime and

602   nighttime are ±0.0206 and ±0.0271, respectively. The difference between them is

603   0.0291, which is larger than the respective 95% confidence intervals. Therefore, the

604   two slopes are not equivalent based on the 95% confidence intervals.

605   However, since the slope of the regression line determined using all of the data is

606   1.0042 and the 95% confidence interval is ±0.0173, the three slopes of the regression

607   lines can be regarded as equivalent at the 95% confidence level. Furthermore, there

608   are no large differences in the bias, RMSE, and correlation coefficient between PWV

609   from the radiosonde and POM-02. Therefore, the PWVs of daytime and nighttime for

610   POM-02 are statistically equivalent. That is, both PWVs are presumed to have the

611   same degree of precision and accuracy within the measurement uncertainty.

612

613   6.2.2 GPS

614

615   Next, the result of the comparison between the PWV obtained from POM-02 and

616   GPS is shown. Before that, the result of the comparison between the PWV obtained

617   from GPS and the radiosonde is shown in Fig. 11. Table 7 shows the results of the

618   comparison between GPS and radiosonde precipitable water vapor (Table 7 is the

619   same as Table 4 except for GPS and radiosonde precipitable water vapor).

620   The slope of the regression line in Fig. 11 is about 0.94. In the region of the PWV

621   less than 2 g/cm², the PWV from GPS tends to be smaller than the PWV from the

622   radiosonde. In the region of PWV more than 3 g/cm², the difference between PWV

623   from GPS and the radiosonde is more scattered. Therefore, the slope of the

624   regression line became smaller than 1. In a previous comparison conducted by the

625   authors, the slope of the regression line was almost 1 (Uchiyama et al. 2014). There

626   is a possibility that the PWV from GPS used in this study has a larger error than the

627   PWV used previously.

628   Figure 12 shows a scatter diagram of the PWV from GPS and the corrected PWV

629   from POM-02. Table 8 shows the results of the comparison between PWV from GPS

630   and corrected PWV from POM-02 (Table 8 is the same as Table 4 except for GPS and

631 corrected POM-02 precipitable water vapor).

632 The slope of the regression line is about 0.91 for both the daytime and nighttime.

633 Similar to the results of the comparison between the PWV from the radiosonde and

634 GPS, in the region of PWV from GPS less than 2 g/cm², the PWV from GPS tends to

635 be somewhat smaller than the PWV from POM-02 during both the daytime and

636 nighttime. In the region of PWV greater than 3 g/cm², the difference between the

637 PWV from GPS and the radiosonde is more scattered.

638 The difference between the slopes of the regression lines is 0.0076 (= 0.9132 −

639 0.9056) and the 95% confidence intervals during the daytime and nighttime are

640 ±0.0097 and ±0.0221, respectively. Therefore, the confidence intervals of the two

641 slopes are overlapping, and the values of slopes can be regarded as equivalent at the

642 95% confidence level.

643 In Fig. 12 (c), the scatter plot obtained using nighttime data is shown together

644 with that obtained using daytime data. The data obtained during the daytime and

645 nighttime overlap, and it seems that the PWV from POM-02 during the daytime and

646 nighttime are estimated with the same degree of precision and accuracy.

647 Examples of time series of PWV from GPS and POM-02 are shown in Fig. 13. The

648 PWV from GPS and that from POM-02 have qualitatively similar time variations. In

649 these limited examples, although there are some systematic differences in Fig. 13 (b),

650 the PWV from GPS and the PWV from POM-02 almost overlap in Figs. 13 (a) and (c).

651 In addition, the PWV during the daytime and nighttime estimated from POM-02 are

652 continuously connected.

653 In Fig. 13, only limited examples were shown, but in the Supplement, the time

654 series of the PWV at Tsukuba for 5 months is shown in Fig. S2. In addition, the time

655 series of the comparison between GPS and POM-02 PWV for 5 months is shown in

656 Fig. S4.

657

658 6.3 Comparison of AOD (PVW) before and after sunrise and sunset

659

660 The comparison of the AOD (PWV) before and after sunrise and sunset is used to

661 evaluate the moon photometry (Berkoff et al. 2011, Barreto et al. 2013, 2016, 2017,

662 2019).

663 Before and after sunrise (sunset), the AOD before sunrise (after sunset) is the

664 average of the data with a solar altitude angle between −10 and −15 degrees, with a

665 lunar phase angle less than 100 degrees, and with a lunar altitude angle of more

666 than 10 degrees. The AOD after sunrise (before sunset) is the average of the data

667 with a solar altitude angle between 10 and 15 degrees. Since this comparison is

668 effective when the atmosphere is stable, only data with small variations were
669 selected; standard deviation / average value is less than 0.1 or standard deviation is
670 less than 0.02.

671   Figure 14 shows a scatter plot of the AOD at the wavelengths of 340, 380, 400, 500,
672 675, 870, and 1020 nm, and the PWV from the 940 nm channel. Table 9 shows the
673 results of the comparison between the AOD (PWV) from the sun and from the moon
674 (The contents of Table 9 are the same as Table 4 except for the AOD (PWV) from the
675 sun and the moon).

676   The biases at wavelengths of 340 and 380 nm are relatively large, 0.05 and 0.03,
677 respectively, but the biases at other wavelengths are 0.007 or less. The bias and
678 RMSE of the PWV are 0.02 and 0.14, respectively, which are comparable to those
679 from the comparison with POM-02 and the radiosonde or GPS. The correlation
680 coefficient is high for all wavelengths; 0.65 at a wavelength of 340 nm, and 0.97 or
681 higher at other wavelengths. Furthermore, the 95% confidence interval of the slope
682 value of the regression line includes 1, and the 95% confidence interval of the
683 intercept value includes 0. That is, the regression line is not different from a straight
684 line with a slope of 1 and zero intercept at the 95% confidence level. From these facts,
685 the AOD and PWV retrieved using the moon as the light source are considered to be
686 the same as those retrieved using the sun as the light source at the 95% confidence
687 level.

688

689 6.4 Comparison between AERONET and POM-02

690

691   There is an AERONET observation site at MLO. In the nighttime, the AODs at
692 wavelengths of 500, 675, 870, and 1020 nm, and the PWV can be compared. In
693 addition to these channels, the AOD at wavelengths of 340, 380, 1020, and 1627 nm
694 can be compared in the daytime. The AERONET data used here are "level 2.0" in the
695 daytime and "level 1.5" in the nighttime. There were no "level 2.0" nighttime data.
696 AERONET "level 1.5" is cloud-screened data but may not have had the final
697 calibration applied. Thus, these data are not quality assured. AERONET "level 2.0"
698 has pre- and post-field calibration applied, cloud-screened, and quality-assured data
699 (see the AERONET homepage, https://aeronet.gsfc.nasa.gov/). The nighttime
700 comparison in this paper uses the AERONET data without quality assurance.

701   Figure 15 shows a scatter plot of the AERONET and POM-02 AOD (PWV). The
702 blue (red) symbols show the daytime (nighttime) data. Both the daytime and the
703 nighttime data are overlaid; the AOD at wavelengths of 500, 675, 870, 1020, 1627 nm,
704 and the PWV from the 940 nm channel. The plotted data are the 15-minute averages.

The number of measurements for POM-02 in a 15-minute interval is 10 to 16, and that for AERONET is 1 to 6. Only POM-02 data showing small variations were selected; (standard deviation)/average is less than 0.1 or standard deviation is less than 0.02.

Table 10 shows the results of the comparison between the AERONET and POM-02 aerosol optical depth (precipitable water vapor) (Table 10 is the same as Table 4 except for AERONET and POM-02 aerosol optical depth (precipitable water vapor)). The values at 940 nm are the precipitable water vapor.

In the daytime, from Fig. 15, it can be seen that the differences between AERONET and POM-02 AOD (PWV) are small. The 95% confidence interval for the slope of the regression line does not necessarily include 1, but the slope value is nearly 1: between 0.97 and 1.11. The 95% confidence interval for the intercept of the regression line does not necessarily include 0, but the magnitude of the intercept is 0.01 or less except for the 380 nm channel (0.015). The same can be said for the PWV of the 940 nm channel. In addition, the bias and RMSE are less than 0.01 except for the 380 nm channel (0.015), and those for the PWV at 940 nm are 0.018 and 0.022, respectively. Considering that the accuracy of the calibration constant is 0.5 to 1%, these values seem reasonable. Therefore, it can be inferred that in the daytime, POM-02 can measure the AOD (PWV) with the same level of accuracy as AERONET.

In the nighttime, the atmosphere observed at MLO was pristine, and most of the AOD at 500, 675, 870, and 1020 nm were below 0.02. Considering that the accuracy of the calibration constant is 0.5 to 1%, it is difficult to compare the AOD of AERONET and POM-02. In the nighttime, the slope of the regression line deviates from 1 at several wavelengths, but the bias and the RMSE are less than about 0.01. Therefore, the difference between AERONET and POM-02 is small. The slopes of the regression line for the PWV of 940 nm channel in the daytime and the nighttime are 1.07 and 1.16, respectively. Thus, the daytime and nighttime values differ. In the results of section 6.3, there is almost no difference between the daytime and nighttime values. Therefore, this difference may be due to the lack of quality control in the nighttime data.

7. Summary and conclusion

Aerosol data are often estimated using the solar direct irradiance and the solar scattered radiance. Therefore, the majority of data on aerosol properties are obtained using daytime measurements, and there are few data available on aerosol characteristics at night. In order to estimate the aerosol optical depth (AOD) and the

21

precipitable water vapor (PWV) during the nighttime using the moon as a light source, POM-02 (Prede Ltd., Japan), which is used to estimate aerosol characteristics during the daytime, was modified.

The current POM-02 has the ability to measure the direct irradiance from the moon for some channels in the visible and near-infrared wavelength region without requiring modification. Several modifications were made to also be able to measure the AOD during the nighttime and expand the measurement ranges.

The amplifier was adjusted so that POM-02 could measure up to about 5×10^{-13} A: allowing the lunar direct irradiance to be measured in the wavelength range of 340 to 1020 nm.

In order to track the moon based on the calculated value, the simplified formula by Nagasawa (1981) was incorporated into the firmware.

A position sensor with a four-quadrant detector is used to adjust the tracking of the sun and the moon. In order to adjust the tracking of the moon, a position sensor incorporating a new electronic circuit to amplify the signal and new software to process the signal data were developed. The new position sensor can be used to track both the sun and the moon.

The calibration constant was determined by using the Langley method. The measurements of the solar and lunar direct irradiance were conducted at the NOAA/MLO during the period from Sep. 28 to Nov. 7, 2017. Assuming that the correct lunar reflectance is proportional to the ROLO reflectance, the calibration constant for the lunar direct irradiance was determined by using the Langley method. The calibration by the Langley method was successfully performed.

The ratio of the calibration constant for the moon to that for the sun was often greater than 1, where the ratio is a coefficient for correcting the ROLO reflectance and includes a smoothing factor. This ratio shows the error of the ROLO irradiance model. The value of the ratio was 0.95 to 1.18 in the visible and near-infrared wavelength region. This means that the ROLO model often underestimates the reflectance. In addition, this ratio depended on the phase angle: when the phase angle was small (near the full moon), the ratio was small, and as the phase angle became larger, the ratio increased. In this study, this ratio was approximated by the quadratic equation of the phase angle. By using this approximation, the reflectance of the moon can be calculated to within an accuracy of 1% or less.

The continuous measurement of POM-02 was conducted at JMA/MRI from January 2018 to May 2018, and the AOD and PWV were estimated. In order to validate the estimates of the AOD and PWV, we compared them with the AOD and PWV obtained by independent methods. The AOD was compared with the AOD (532

nm) estimated from NIES/HSRL, and the PWV was compared with the PWV from a radiosonde and GPS. In addition, the continuity of the AOD (PVW) before and after sunrise and sunset at Tsukuba was examined, and the AOD (PWV) of AERONET and that of POM-02 at MLO were compared.

Concerning the AOD, there were sometimes systematic differences between NIES/HSRL and POM-02. The cause of the systematic differences seems to be that NIES/HSRL assumes a constant extinction coefficient at altitudes of less than 500 m. The slopes of the linear regression lines during the daytime and nighttime could not be said to be equivalent at the 95% confidence level, but the scatter diagrams of the daytime and nighttime were almost overlapping.

Concerning the PWV, the slopes of the linear regression lines during the daytime and nighttime were equivalent at the 95% confidence level in the comparisons between the PWV from POM-02 and the radiosonde and in the comparison between the PWV from POM-02 and GPS. Furthermore, the scatter diagrams of the daytime and the nighttime data were almost overlapping.

In addition, the comparison of the AOD (PWV) before and after sunrise and sunset showed that the AOD and PWV retrieved using the moon as the light source are the same as those retrieved using the sun as the light source at the 95% confidence level.

The comparison of the AOD (PWV) between AERONET and POM-02 was performed using the data taken during the calibration measurements. The comparison in the daytime showed that POM-02 can measure AOD (PWV) with the same accuracy as AERONET. The comparison in the nighttime showed that the difference in the AOD between AERONET and POM-02 was small. However, since there were a lot of optically thin data and AERONET data are not quality-assured, we cannot make a definite conclusion.

From these facts, the daytime and nighttime AOD (PWV) measurements are statistically almost equivalent. The AODs (PWVs) during the daytime and nighttime for POM-02 are presumed to have the same degree of precision and accuracy within the measurement uncertainty.

The accuracy of the nighttime calibration constant is lower than that for the daytime. The measurement S/N in the nighttime is also worse than that in daytime. Considering these facts, even if there is no statistically significant difference, the magnitude of the error in the AOD (PWV) during the nighttime is not always the same as during the daytime.

In this study, the calibration was performed using about 40 days of data including two full moon days. As a result, it was found that there was an error in the reflectance of the ROLO irradiance model. In the future, it is necessary to

816 accumulate more data for calibration and to reduce the error of the ROLO irradiance
817 model. It is said that the ROLO model can be applied over a phase angle range of
818 about 90 degrees. POM-02 has the ability to measure the direct lunar irradiance up
819 to a phase angle range of about 120 degrees. It is necessary to expand the ROLO
820 irradiance model so that it can be applied to larger phase angles.

821   It is now possible to estimate the aerosol optical depth during the nighttime. It is
822 necessary to promote the adoption of this system in the existing observation network.
823 After that, the data obtained by using this instrument can be used to better
824 understand nighttime aerosol behavior, for the validation of aerosol transport models,
825 and as input data in assimilation systems.

826

827

828 **Appendix A.**

829   The smoothed ROLO reflectance $\tilde{A}_{ROLO}$ can be obtained by the procedure described

830 in Kieffer and Stone (2005).

831   The calculated reflectance $A_{ROLO}(g, \Phi, \theta, \phi)$ at the 32 ROLO wavelengths for a
832 specific geometric configuration $(g = 7 \deg, \Phi = 7 \deg, \theta = 0, \phi = 0)$ is fitted to a
833 composite spectrum of the samples obtained by the Apollo 16 mission with a linear
834 equation of wavelength λ.

835     $A_{Apollo} = (a + b\lambda)A_{ROLO}(7,7,0,0)$ (a1)

836 where A_{Apollo} is the composite laboratory reflectance spectrum for the Apollo samples
837 of soil (95%) (Apollo 16 sample 62231, (Pieters 1999)) and breccia (5%) (Apollo 16
838 sample 67455 (Pieters and Mustard 1988)).

839 The   Apollo   sample   62231   spectrum   is   available   at
840 http://www.planetary.brown.edu/pds/AP62231.html. The   Apollo   sample   67455
841 spectrum is shown in Fig. 8 in the paper of Pieters and Mustard (1988).

842   The values of the coefficients a and b are not shown in Kieffer and Stone (2005),
843 but were determined here with the least squares method as follows:

844     $a = 1.640875$

845     $b = -1.192034 \times 10^{-4}$

846 where the unit of the wavelengths is nanometers.

847 By dividing A_{Apollo} by $a + b\lambda$, the smoothed ROLO reflectance for a specific

848 geometric configuration $\tilde{A}_{ROLO}(7,7,0,0)$ can be obtained.

849 $$\tilde{A}_{ROLO}(7,7,0,0) = A_{Apollo} / (a + b\lambda) \qquad \text{(a2)}$$

850 The smoothed ROLO reflectance $\tilde{A}_{ROLO}(g,\Phi,\theta,\phi)$ for any viewing geometry is

851 given by the following equation:

852 $$\begin{aligned} \tilde{A}_{ROLO} &= \frac{\tilde{A}_{ROLO}(7,7,0,0)}{A_{ROLO}(7,7,0,0)} A_{ROLO}(g,\Phi,\theta,\phi) \\ &= F_C A_{ROLO}(g,\Phi,\theta,\phi) \end{aligned} \qquad \text{(a3)}$$

853 where $F_C = \tilde{A}_{ROLO}(7,7,0,0) / A_{ROLO}(7,7,0,0)$.

854 The values of F_C are dependent on the interpolation method of the reflectance

855 table and the accuracy of the values read from the figure. The smoothed and adjusted

856 spectrum $\tilde{A}_{ROLO}(7,7,0,0)$ is shown in Fig. A1. The values of F_C determined by the

857 authors are shown in Table A1 and Fig. A2.

860 **Data availability.**

861 The data used in this study are available from the corresponding author.

862

863 **Author contributions.**

864 This study was designed by AU, MS, HK, and TM. The measurements for the sky

865 radiometer were conducted by AU, AK, KI, and YW. The adjustment of the amplifier

866 and the development of the position sensor were performed by MS, HK, KI, KK, and

867 YW. The development of the related software and the data analyses were performed

868 by AU. The manuscript was written by AU, and all authors contributed to editing

869 and revision.

Supplement

The time series of the AOD at 500 nm and PWV at Tsukuba for 5 months are shown in Fig. S1 and Fig. S2, respectively. These are non-cloud screened data.

In addition, the time series of the comparison between HSRL and POM-02 AOD and the time series of the comparison between GPS and POM-02 PWV are shown in Fig. S3 and Fig. S4.
